Do we know how birds evolved? The evolution of birds is arguably one of the most interesting chapters in Earth's history of life. Given the substantial fossil evidence, most paleontologists have concluded that the ancestors of birds were dinosaurs, specifically the *dromaeosaurs*, a group of ground-dwelling, bipedal theropods (carnivorous saurischians). Beginning in 1997, paleontologists made several discoveries of fossil dinosaurs with feathers, indicating that feathers appeared before birds. Scientists think that feathers evolved as one or a series of evolutionary novelties, or **preadaptations** (see Chapter 20). The first feathers may have provided thermal insulation but were subsequently modified for flight.

Once dinosaurs and early birds had feathers, how did they fly? Did tree-dwelling animals glide as an intermediate step in bird flight, or did ground-dwelling animals flap their wings and run to provide thrust and lift for a takeoff? The question about how flight originated in birds has intrigued biologists for more than a century. In 1915, U.S. zoologist William Beebe hypothesized that the ancestors of birds were probably tree-dwelling gliders that had feathers on all four limbs.¹ Because no fossil evidence supported his suggestion, scientists did not consider it seriously at the time.

Almost a century later, in 2003, a group of Chinese paleontologists announced the discovery of two nearly complete fossils of the organisms that Beebe had hypothesized.² The

fossils of a small, feathered dromaeosaur dinosaur were found in Liaoning Province in northeastern China. The dinosaur, *Microraptor gui*, had feathers on both forelimbs and hind limbs as well as on its long tail. The figure depicts light-colored feathers to better illustrate their details, but analysis of melanosomes (pigment-containing bodies) in fossils has shown that the plumage was iridescent black, as in crows today. It was small—77 cm (about 30 in.) in length, including the tail—and appeared to be adapted to life in the trees. The feathers on *M. gui* were similar to those of modern-day birds. Downy feathers covered the body, and each limb had about 12 “primary” flight feathers and about 18 shorter, “secondary” feathers. *Microraptor gui*'s flight feathers were asymmetrical, a characteristic associated with flight or gliding in modern birds. The primary and secondary feathers followed a similar pattern on both the forelimbs and hind limbs, and this pattern resembles that on modern birds. In part because *M. gui*'s breastbone was not structured to attach large flight muscles, the dinosaur probably glided rather than flapped its wings.

Microraptor gui, which is about 126 million years old, is not a direct ancestor of birds. Birds had already evolved when *M. gui* existed. The earliest known bird, *Archaeopteryx*, lived about 150 mya and therefore predates *M. gui* by about 25 million years. *Microraptor gui* is considered to have evolved from a *basal member*—that is, an earlier evolutionary branch—of the most recent ancestor of *Archaeopteryx* and

Journal Nature/Portia Sloan/Getty Images

other birds. Like *M. gui*, earlier feathered dinosaurs may have been four-winged organisms that lived and glided in the trees.

During the course of bird evolution, the feathered hind limbs may have become reduced and eventually lost. However, an alternative hypothesis is that feathered hind limbs may have been a failed evolutionary experiment restricted to dromaeosaurs and not important as an intermediate step in bird evolution. Further analysis of *M. gui* and future discoveries of earlier dromaeosaur fossils may shed some light on the importance of feathered hind limbs.

Microraptor gui has given paleontologists and biologists much to consider in the evolutionary transition from dinosaurs to birds. Scientists will continue to study and debate the evolution of flight in birds for many years.

² Xu, X., Z. Zhou, X. Wang, X. Kuang, F. Zhang, and X. Du, “Four-Winged Dinosaurs from China,” *Nature*, Vol. 421 (Jan. 23, 2003).

The Chicxulub crater, buried under the Yucatán Peninsula in Mexico, is the apparent site of this collision. The impact produced giant tsunamis (tidal waves) that deposited materials from the extraterrestrial body around the perimeter of the Gulf of Mexico, from Alabama to Guatemala. It may have caused global forest fires and giant smoke and dust clouds that lowered global temperatures for many years.

Although scientists widely accept that a collision with an extraterrestrial body occurred 66 mya, they have reached no consensus about the effects of such an impact on organisms. The extinction of many marine organisms at or immediately after the time of the impact was probably the result of the environmental upheaval that the collision produced. However, many clam species associated with the mass extinction at the end of the Cretaceous period seem to have gone extinct *before* the impact, suggesting that other factors caused some of the massive extinctions occurring then.

The Cenozoic era is the Age of Mammals

With equal justice the Cenozoic era could be called the Age of Mammals, the Age of Birds, the Age of Insects, or the Age of Flowering Plants. This era is marked by the appearance of all these forms in great variety and numbers of species. The Cenozoic era extends from 66 mya to the present. It is subdivided into three periods: the **Paleogene period**, encompassing some 43 million years; the **Neogene period**, which was 20.4 million years in length; and the **Quaternary period**, which covers the last 2.6 million years. The Paleogene period is subdivided into three epochs, named from earliest to latest: Paleocene, Eocene, and Oligocene. The Neogene period is subdivided into two epochs: the Miocene and Pliocene. The Quaternary period is subdivided into the Pleistocene and Holocene epochs.

Flowering plants, which arose during the Cretaceous period, continued to diversify during the Cenozoic era. During

the Paleocene and Eocene epochs, fossils indicate that tropical and semitropical plant communities extended to relatively high latitudes. Palms, for example, are found in Eocene deposits in Wyoming. Later in the Cenozoic era, there is evidence of more open habitats. Grasslands and savannas spread throughout much of North America during the Miocene epoch, with deserts developing later in the Pliocene and Pleistocene epochs. During the Pleistocene epoch, plant communities changed dynamically in response to the fluctuating climates associated with the multiple advances and retreats of continental glaciers.

During the Paleocene epoch, an explosive radiation of primitive mammals occurred. Most of them were small forest dwellers that are not closely related to modern mammals. During the Eocene epoch, mammals continued to diverge, and all the modern orders first appeared. Again, many of the mammals were small, but there were also some larger herbivores.

During the Eocene epoch, there was an explosive radiation of birds, which acquired adaptations for different habitats. Paleontologists hypothesize that the jaws and beak of the flightless giant bird *Diatryma*, for example, may have been adapted primarily for crushing and slicing vegetation in Eocene forests, marshes, and grasslands. Other paleontologists hypothesize that these giant birds were carnivores that killed or scavenged mammals and other vertebrates (FIG. 21-17).

During the Oligocene epoch, many modern families of mammals evolved, including the first apes in Africa. Many lineages showed adaptations that suggest a more open type of habitat, such as grassland or savanna, than previously. Many mammals were larger than earlier mammals and had longer legs for running, specialized teeth for chewing coarse vegetation or for preying on animals, and increases in their relative brain sizes. The *indricotheres*, for example, are extinct relatives of the rhinoceros. These mammals, which lived on the grassless plains of Eurasia, became progressively larger during the Oligocene epoch (FIG. 21-18).

Figure 21-18 A mammal from the Oligocene epoch
Paraceratherium was an indricothere, a hornless relative of the rhinoceros. This huge land mammal was about 8 m (26 ft) long and weighed about 15 to 20 tons. It probably ate leaves and branches of deciduous trees, much as a modern-day giraffe does.

Human ancestors appeared in Africa during the Late Miocene and Early Pliocene epochs. *Homo*, the genus to which humans belong, appeared approximately 2.5 mya. (Primate evolution, including human evolution, is discussed in Chapter 22.)

The Pliocene and Pleistocene epochs witnessed the introduction of spectacular North and South American large-mammal fauna, including mastodons, saber-toothed cats, camels, giant ground sloths, and giant armadillos. However, many of the large mammals became extinct at the end of the Pleistocene epoch. This extinction was possibly due to climate change—the Pleistocene epoch was marked by several ice ages—or to the influence of humans, which had spread from Africa to Europe and Asia, and later to North and South America by crossing a land bridge between Siberia and Alaska. Archaeological evidence indicates that this mass extinction event was concurrent with the appearance of human hunters.

Recognition of the profound impact humans have had on Earth has led some scientists to propose a new geological epoch, the Anthropocene, or “Age of Humans.” This hypothesis will be explored in more detail in Chapter 57.

Figure 21-17 A bird from the Eocene epoch
The flightless bird *Diatryma*, which stood 2.1 m (7 ft) tall and weighed about 175 kg (385 lb), may have been an herbivore or a formidable predator. In this picture *Diatryma* has captured a small, horselike perissodactyl.

Summary: Focus on Learning Objectives

21.1 Chemical Evolution on Early Earth (page 443)

1 Describe the conditions that scientists think existed on early Earth.

- Biologists generally agree that life originated from nonliving matter by **chemical evolution**. Hypotheses about chemical evolution are testable.
- Four requirements for chemical evolution are (1) the absence of oxygen, which would have reacted with and oxidized abiotically produced organic molecules; (2) energy to form organic molecules; (3) chemical building blocks, including water, minerals, and gases present in the atmosphere; and (4) sufficient time for molecules to accumulate and react.

2 Compare the prebiotic soup hypothesis with the iron–sulfur world hypothesis.

- During chemical evolution, small organic molecules formed spontaneously and accumulated. The **prebiotic soup hypothesis** proposes that organic molecules formed near Earth's surface in a "sea of organic soup" or on rock or clay surfaces. The **iron–sulfur world hypothesis** suggests that organic molecules were produced at **hydrothermal vents**, cracks in the deep-ocean floor.

21.2 The First Cells (page 445)

3 Outline the major steps hypothesized to have occurred in the origin of cells.

- After small organic molecules formed and accumulated, macromolecules assembled from the small organic molecules. Macromolecular assemblages called **protobionts** formed from macromolecules. Cells arose from the protobionts.
- According to a model known as the **RNA world**, RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell. Natural selection at the molecular level eventually resulted in the information sequence DNA → RNA → protein.

4 Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.

- The first cells were prokaryotes and were almost certainly **anaerobes**.
- The evolution of oxygen-generating photosynthesis ultimately changed early life. The accumulation of molecular oxygen in the atmosphere permitted the evolution of **aerobes**, organisms that could use oxygen for a more efficient type of cellular respiration.

5 Describe the hypothesis of serial endosymbiosis.

- Eukaryotic cells arose from prokaryotic cells. According to the hypothesis of **serial endosymbiosis**, certain eukaryotic organelles (mitochondria and chloroplasts) evolved from prokaryotic **endosymbionts** incorporated within larger prokaryotic hosts.

21.3 The History of Life (page 451)

6 Briefly describe the distinguishing organisms and major biological events of the Ediacaran period and the Paleozoic, Mesozoic, and Cenozoic eras.

- Life at the beginning of the **Proterozoic eon** (2500 mya to 541 mya) consisted of prokaryotes. About 2.2 bya, the first eukaryotic cells appeared. The **Ediacaran period**, from 635 mya to 541 mya, is the last period of the Proterozoic eon. Ediacaran fossils are the oldest known fossils of multicellular animals. Ediacaran fauna were small, soft-bodied invertebrates.
- During the **Paleozoic era**, which began about 541 mya and lasted approximately 289 million years, all major groups of plants, except flowering plants, and all animal phyla appeared. Fishes and amphibians flourished, and reptiles appeared. The greatest mass extinction of all time occurred at the end of the Paleozoic era, 252 mya. More than 90% of marine species and 70% of land-dwelling vertebrate genera as well as many plant species became extinct.
- The **Mesozoic era** began about 252 mya and lasted some 186 million years. Flowering plants appeared, and reptiles diversified. Dinosaurs, which descended from early reptiles, dominated. Insects flourished, and birds and early mammals appeared. At the end of the Cretaceous period, 66 mya, many species abruptly became extinct. A collision of a large extraterrestrial body with Earth may have resulted in dramatic climate changes that played a role in this mass extinction.

- In the **Cenozoic era**, which extends from 66 mya to the present, flowering plants, birds, insects, and mammals diversified greatly. Human ancestors appeared in Africa during the Late Miocene and Early Pliocene epochs.

Test Your Understanding

Know and Comprehend

1. Energy, the absence of molecular oxygen, chemical building blocks, and time were the requirements for (a) chemical evolution (b) biological evolution (c) the Cambrian radiation (d) the mass extinction episode at the end of the Cretaceous period (e) directed evolution
2. Many scientists think that _____ was the first information molecule to evolve. (a) DNA (b) RNA (c) a protein (d) an amino acid (e) a lipid
3. The first cells were probably (a) photosynthetic (b) aerobes (c) anaerobes (d) a and b (e) a and c

4. According to the hypothesis of serial endosymbiosis, (a) life originated from nonliving matter (b) the pace of evolution quickened at the start of the Cambrian period (c) chloroplasts, mitochondria, and possibly other organelles originated from intimate relationships among prokaryotic cells (d) banded iron formations reflect the buildup of sufficient oxygen in the atmosphere to oxidize iron at Earth's surface (e) the first photosynthetic organisms appeared 3.1 bya to 3.5 bya
5. During the Early _____, life consisted of prokaryotic cells, but by the end of this geologic time span, multicellular eukaryotic organisms had evolved. (a) Cenozoic era (b) Paleozoic era (c) Mesozoic era (d) Archaean eon (e) Proterozoic eon
6. Geologists divide the eons into (a) periods (b) epochs (c) eras (d) millennia (e) none of the preceding
7. Ediacaran fossils (a) are the oldest known fossils of multicellular animals (b) come from the Burgess Shale in British Columbia (c) contain remains of large salamander-like organisms (d) are the oldest fossils of early vascular plants (e) contain a high concentration of iridium
8. The time of greatest evolutionary diversification in the history of life occurred during the (a) Cambrian period (b) Ordovician period (c) Silurian period (d) Carboniferous period (e) Permian period
9. The greatest mass extinction episode in the history of life occurred at what boundary? (a) Pliocene–Pleistocene (b) Permian–Triassic (c) Mesozoic–Cenozoic (d) Cambrian–Ordovician (e) Triassic–Jurassic
10. The Age of Reptiles corresponds to the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Pleistocene epoch (e) Permian period
11. Evidence exists that a catastrophic collision between Earth and a large extraterrestrial body occurred 66 mya, resulting in the extinction of (a) worms, mollusks, and soft-bodied arthropods (b) jawless ostracoderms and jawed placoderms (c) dinosaurs, pterosaurs, and many gymnosperm species (d) mastodons, saber-toothed cats, and giant ground sloths (e) ferns, horsetails, and club mosses
12. Flowering plants and mammals diversified and became dominant during the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Devonian period (e) Cambrian period

Apply and Analyze

13. Which are thought to have evolved first, aerobic bacteria or photosynthetic bacteria? Explain.

Evaluate and Synthesize

14. **EVOLUTION LINK** If you were studying how protobionts evolved into cells and you developed a protobiont that was capable of self-replication, would you consider it a living cell? Why or why not?
15. **EVOLUTION LINK** If living cells were produced in a test tube from nonbiological components by chemical processes, would this accomplishment prove that life evolved in a similar manner billions of years ago? Explain your answer.
16. **EVOLUTION LINK** Why did the evolution of multicellular organisms such as plants and animals have to be preceded by the evolution of oxygen-producing photosynthesis?
17. **INTERPRET DATA** Evidence for the oldest cyanobacterial fossils (as stromatolites) dates to about 2 billion years, but molecular evidence inferred from lipids in ancient rocks puts the date for living cyanobacteria and eukaryotes at 2.7 billion years. Develop two opposing hypotheses to explain the discrepancy between the dates.

22 The Evolution of Primates

Twelve years after Darwin wrote *On the Origin of Species by Means of Natural Selection*, he published another controversial book, *The Descent of Man*, which addressed human evolution. In this later book, Darwin hypothesized that humans and apes share a common ancestry. For nearly a century after Darwin's studies, fossil evidence of human ancestry remained fairly incomplete. However, research during the last several decades, especially in Africa, has yielded a rapidly accumulating set of fossils that gives an increasingly clear answer to the question, Where did we come from?

Fossil evidence from **paleoanthropology**, the study of human evolution, has allowed scientists to infer not only the structure but also the habits of early humans and other primates. Teeth and bones are the main fossil evidence that paleoanthropologists study (see photograph). Much information can be obtained by studying teeth, which have changed dramatically during the course of primate and human evolution. Because tooth enamel is more mineralized (harder) than bone, teeth are more likely to fossilize. The teeth of each primate species, living or extinct, are distinctive enough to identify the species, approximate age, diet, and even sex of the individual.

Based on fossil evidence, paleontologists hypothesize that the first primates descended from small, shrewlike *placental mammals* that lived in trees and ate insects. (Placental mammals are the largest and most successful group of mammals. They have a **placenta**, an organ that exchanges materials between the mother and the embryo/fetus developing in the uterus.)

KEY CONCEPTS

- 22.1** Humans, along with lemurs, tarsiers, monkeys, and apes, are classified in the order Primates. This classification is based on close evolutionary ties.
- 22.2** The study of living primates provides clues to help scientists reconstruct the adaptations and lifestyles of early primates, some of which were ancestors of humans.
- 22.3** Fossil evidence indicates that the earliest human ancestors arose in Africa and shared many features with their apelike ancestors. The human brain did not begin to enlarge to its present size and complexity until long after bipedal locomotion had evolved.
- 22.4** Human culture began when human ancestors started making stone tools.

Many traits of the 233 generally recognized living primate species are related to their **arboreal** (tree-dwelling) past. This chapter focuses on humans and their ancestors, who differ from most other primates because they did not remain in the trees but instead adapted to a terrestrial way of life.

22.1 Primate Adaptations

LEARNING OBJECTIVE

- 1 Describe the structural adaptations that primates have for life in treetops.

Humans and other **primates**—including lemurs, tarsiers, monkeys, and apes—are mammals that share such traits as flexible hands and feet with five digits, a strong social organization, and front-facing eyes, which permit depth perception. Mammals (class Mammalia) evolved from mammal-like reptiles known as *therapsids* more than 200 million years ago (mya), during the Mesozoic era (see Fig. 32-24). These early mammals remained a minor component of life on Earth for almost 150 million years and then rapidly diversified during the Cenozoic era (from 66 mya to the present).

Fossil evidence indicates that the first primates with traits characteristic of modern primates appeared by the Early Eocene epoch about 56 mya. These early primates had digits with nails, and their eyes were directed somewhat forward on the head.

Several novel adaptations evolved in early primates that allowed them to live in trees. One of the most significant primate features is that each limb has five highly flexible digits: four lateral digits (fingers) plus a partially or fully opposable first digit (thumb and, in many primates, big toe; **FIG. 22-1**). An **opposable thumb** positions the fingers opposite the thumb, enabling primates to grasp objects such as tree branches with precision. Nails (instead of claws) provide a protective covering for the tips of the digits, and the fleshy pads at the ends of the digits are sensitive to touch. Another arboreal feature is long, slender limbs that rotate freely at the hips and shoulders, giving primates full mobility to climb and search for food in the treetops.

Having eyes located in the front of the head lets primates integrate visual information from both eyes simultaneously; they have **stereoscopic** (three-dimensional) vision, which is important in judging distance and in depth perception. Stereoscopic vision is vital in an arboreal environment, especially for species that leap from branch to branch, because an error in depth perception may cause a fatal fall. In addition to having sharp sight, primates hear acutely.

Primates share several other characteristics, including a relatively large brain. Biologists have suggested that the increased sensory input associated with primates' sharp vision and greater agility favored the evolution of larger brains. Primates are generally very social and intelligent animals that reach sexual maturity relatively late in life. They typically have long lifespans. Females usually bear one offspring at a time; the baby is helpless and requires a long period of nurturing and protection.

Key Point

Primates have five grasping digits at the end of each limb, and the thumb or first toe is often partially or fully opposable.

CHECKPOINT 22.1

- **CONNECT** What features of primate hands and feet are adaptations to an arboreal existence?
- **CONNECT** What anatomical feature confers stereoscopic vision on primates?

22.2 Primate Classification

LEARNING OBJECTIVES

- 2 List the three suborders of primates and give representative examples of each.
- 3 Distinguish among anthropoids, hominoids, and hominins.

Now that we have surveyed the general characteristics of primates, let us look at how they are classified. Many biologists currently divide the order Primates into three groups, or

Key Point

Several kinds of data support the hypothesis that chimpanzees are the closest living relative of humans.

Figure 22-2 Primate evolution

This branching diagram, called a cladogram, shows evolutionary relationships among living primates, based on current scientific evidence. The nodes (*circles*) represent branch points where a species splits into two or more lineages. The divergence of orangutans from the ape/hominin line occurred some 12 mya to 16 mya. Gorillas separated from the chimpanzee/hominin line an estimated 8 mya, and the hominin (human) lineage diverged from that of chimpanzees about 6 mya. *Figures not drawn to scale.*

CONNECT According to the cladogram, which non-human primates are the closest living relatives of chimpanzees?

suborders (**FIG. 22-2**). The suborder Prosimii includes lemurs, galagos, and lorises; the suborder Tarsiiformes includes tarsiers; and the suborder Anthropeidea includes **anthropoids** (monkeys, apes, and humans).

All lemurs are restricted to the island of Madagascar off the coast of Africa. Because of extensive habitat destruction and hunting, they are very endangered. Lorises, which live in tropical areas of Southeast Asia and Africa, resemble lemurs in many respects, as do galagos, which live in sub-Saharan Africa. Lemurs, lorises, and galagos have retained several early mammalian features, such as elongated, pointed faces.

Tarsiers are found in rain forests of Indonesia and the Philippines (**FIG. 22-3**). They are small primates (about the size of a small rat) and are very adept leapers. These nocturnal primates resemble anthropoids in several ways, including their shortened snouts and forward-pointing eyes.

Suborder Anthropeidea includes monkeys, apes, and humans

Anthropoid primates arose during the Middle Eocene epoch, at least 45 mya. Several different fossil anthropoids have been identified, from Asia and North Africa, and there is a growing consensus about the relationships of these fossil groups to one another and to living anthropoids. Evidence indicates that anthropoids originated in Africa or Asia. The oldest known anthropoid fossils, such as 42-million-year-old *Eosimias*, have been found in China and Myanmar. Given details about their dentition and the few bones that have been discovered, scientists infer that *Eosimias* and other ancestral anthropoids were small, insect-eating arboreal primates that were active during the day. Once they evolved, anthropoids quickly spread throughout Europe, Asia, and Africa and

arrived in South America much later. (Paleoanthropologists date the oldest known South American primate, *Branisella*, from Bolivia, at 26 million years old.)

One significant difference between anthropoids and other primates is the size of their brains. The cerebrum in particular is more developed in monkeys, apes, and humans, where it functions as a highly complex center for learning, voluntary movement, and interpretation of sensation.

Monkeys are generally diurnal (active during the day) tree dwellers. They tend to eat fruit and leaves, with nuts, seeds, buds, insects, spiders, birds' eggs, and even small vertebrates playing a smaller part in their diets. The two main groups of monkeys, New World monkeys and Old World monkeys, are named for the hemispheres where they diversified. Monkeys in South America and Central America are called New World monkeys, whereas monkeys in Africa, Asia, and Europe are called Old World monkeys. New World and Old World monkeys have been evolving separately for tens of millions of years.

One of the most important and interesting questions in anthropoid evolution concerns *how* monkeys arrived in South America. Africa and South America had already drifted apart. (Continental drift is presented in Figure 18-11.) The ancestors of New World monkeys may have rafted from Africa to South America on floating masses of vegetation. The South Atlantic Ocean would have been about half as wide as it is today, and islands could have provided "stepping stones." Once established in the New World, these monkeys rapidly diversified.

New World monkeys are restricted to Central America and South America and include marmosets, capuchins, howler monkeys, squirrel monkeys, and spider monkeys. New World monkeys are arboreal, and some have long, slender limbs that permit easy movement in the trees (FIG. 22-4a). A few have **prehensile tails** capable of wrapping around branches and serving as fifth limbs. Some New World monkeys have shorter thumbs, and in certain cases the thumbs are totally absent (see Fig. 22-1c). Their facial anatomy differs from that of the Old World monkeys; New World monkeys have flattened noses with the nostrils opening to the side. They live in groups and engage in complex social behaviors.

Old World monkeys are distributed in tropical parts of Africa and Asia. In addition to baboons and macaques (pronounced "muh-kacks"), the Old World group includes guenons, mangabeys, langurs, and colobus monkeys. Most Old World monkeys are arboreal, although some, such as baboons and macaques, spend much of their time on the ground (FIG. 22-4b). The ground dwellers, which are **quadrupedal** (four footed; they walk on all fours), arose from arboreal monkeys. None of the Old

(b) Old World monkey. The Anubis baboon (*Papio anubis*) is native to Africa. Note that its nostrils are directed downward.

Figure 22-4 New World and Old World monkeys

World monkeys has a prehensile tail, and some have extremely short tails. They have a fully opposable thumb, and unlike the New World monkeys, their nostrils are closer together and directed downward. Old World monkeys are intensely social animals.

Apes are our closest living relatives

Old World monkeys shared a common ancestor with the **hominoids**, a group composed of apes and **hominins** (humans and their ancestors; also called *hominids*). A fairly primitive anthropoid, discovered in Egypt, was named *Aegyptopithecus* (FIG. 22-5a). A cat-sized, forest-dwelling arboreal monkey with a few apelike characteristics, *Aegyptopithecus* lived during the Oligocene epoch, approximately 34 mya.

Fossil evidence reported in 2010 indicates that apes and Old World monkeys had diverged between 29 mya and 28 mya. During the Miocene epoch, as many as one hundred species of apes lived in Africa, Asia, and Europe.

Paleoanthropologists have discovered the oldest fossils with hominoid features in East Africa, mostly in Kenya. *Proconsul*, for example, appeared early in the Miocene epoch, about 20 mya (FIG. 22-5b). It had a larger brain than that of monkeys and apelike teeth and diet (fruits), but a monkeylike body. At least 30 other early hominoid species lived during the Miocene epoch, but most of them became extinct and were not the common ancestor of modern apes and humans.

Miocene fossils of forest-dwelling, chimpanzee-sized apes called *dryopithecines*, which lived about 15 mya, are of special interest because this hominoid lineage may have given rise to modern apes as well as to humans (FIG. 22-5c). The dryopithecines, such as *Dryopithecus*, *Kenyapithecus*, and *Morotopithecus*, were distributed widely across Europe, Africa, and Asia. As the climate gradually cooled and became drier, their range became more limited. These apes had highly modified bodies for swinging through the branches of trees, although there is also evidence that some of them may have left the treetops for the ground as dense forest gradually changed into open woodland. Many questions about the relationships among the various early apes have been generated by the discovery of these and other Miocene hominoids. As future fossil finds are evaluated, they may lead to a rearrangement of ancestors in the hominoid family tree.

Five genera of hominoids exist today: gibbons (*Hylobates*), orangutans (*Pongo*), gorillas (*Gorilla*), chimpanzees (*Pan*), and humans (*Homo*). Gibbons are known informally as lesser apes; orangutans, gorillas, and chimpanzees are known as great apes. Molecular evidence indicates a close relationship between humans and the great apes, particularly chimpanzees.

Gibbons are natural acrobats that can *brachiate*, or arm-swing, with their weight supported by one arm at a time (FIG. 22-6a). Orangutans are also tree dwellers, but chimpanzees and especially gorillas have adapted to life on the ground (FIGS. 22-6b–d). Gorillas and chimpanzees have retained long arms typical of brachiating primates but use them to assist in quadrupedal walking, sometimes known as *knuckle walking*

(a) Fossils of *Aegyptopithecus*, a fairly primitive anthropoid, were discovered in Egypt.

(b) Skeletal reconstruction of *Proconsul*. (The reconstructed parts are white.) This anthropoid had the limbs and body proportions of a monkey but lacked a tail, like all apes.

(c) *Dryopithecus*, a more advanced ape, may have been ancestral to modern hominoids.

because of the way they fold (flex) their digits when moving. Like humans, apes lack tails, a characteristic that makes them easy to distinguish from monkeys. They are generally much larger than monkeys, although gibbons are a notable exception.

Figure 22-6 Apes

Molecular data provide clues about evolution of anthropoid primates Evidence of the close relatedness of orangutans, gorillas, chimpanzees, and humans is abundant at the molecular level. The amino acid sequence of the chimpanzee's hemoglobin is identical to that of the human; hemoglobin molecules of the gorilla and rhesus monkey differ from the human's by 2 and 15 amino acids, respectively. DNA sequence analyses indicate that chimpanzees are likely to be our nearest living relatives among the apes. (Figure 18-18 shows the percent divergence in a non-protein-coding sequence on the β -globin gene between various primates, including the apes, and humans.)

Researchers have sequenced the genomes of many primates, including all the great apes. Molecular evidence suggests

that orangutans may have diverged from the gorilla, chimpanzee, and hominin lines about 12 mya to 16 mya. Gorillas may have diverged from the chimpanzee and hominin lines some 10 mya, whereas chimpanzee and hominin lines probably separated about 4 mya.

22.3 Hominin Evolution

LEARNING OBJECTIVES

- 4 Describe skeletal and skull differences between apes and hominins.
- 5 Briefly describe the following early hominins: *Orrorin*, *Ardipithecus*, *Australopithecus anamensis*, *Au. afarensis*, *Au. africanus*, and *Au. sediba*.
- 6 Distinguish among the following members of genus *Homo*: *H. habilis*, *H. ergaster*, *H. erectus*, *H. antecessor*, *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens*.
- 7 Discuss the origin of modern humans.

Scientists have a growing storehouse of hundreds of hominid fossils, which provide useful data about general trends in the body design, appearance, and behavior of ancestral humans. Despite the wealth of fossil evidence and a growing body of molecular data, scientists continue to vigorously debate interpretations of hominid characteristics, classification, and evolution. New discoveries will continue to raise new questions.

Evolutionary changes from the earliest hominins to modern humans are evident in some of the characteristics of the skeleton and skull. For example, before their brains enlarged, early hominins clearly adopted a **bipedal** (two-footed) posture. Compared with the ape skeleton, the human skeleton shows distinct differences that reflect humans' ability to stand erect and walk on two feet (FIG. 22-7). These differences also reflect the habitat change for early hominins, from an arboreal existence in the forest to a life spent at least partly on the ground.

The curvature of the human spine provides better balance and weight distribution for bipedal locomotion than the spine of the ape. The human pelvis is shorter and broader than the ape pelvis, allowing better attachment of muscles used for upright walking. (The shape of the human pelvis also allows the birth of offspring with large brains.) In apes the **foramen magnum**, the hole in the base of the skull for the spinal cord, is located in the rear of the skull. In contrast, the human foramen magnum is centered in the skull base, positioning the head for erect walking. An increase in the length of the legs relative to the arms and alignment of the first toe with the rest of the toes further adapted the early hominins for bipedalism.

Figure 22-7 Gorilla and human skeletons

When gorilla and human skeletons are compared, the skeletal adaptations for bipedalism in humans become apparent.

Another major trend in hominin evolution was an increase in brain size relative to body size (FIG. 22-8). The ape skull has prominent **supraorbital ridges** above the eye sockets, whereas modern human skulls lack these ridges. Human faces are flatter than those of apes, and the jaws are different. The arrangement of teeth in the ape jaw is somewhat rectangular, compared with a rounded, or U-shaped, arrangement in humans. Apes have larger front teeth (canines and incisors) than do humans, and their canines are especially large. Gorillas and orangutans also have larger back teeth (premolars and molars) than do humans.

We now examine some of the increasing number of fossil hominins in the human lineage. As you read the following descriptions of human evolution, keep in mind that much of what is discussed is open to reinterpretation and major revision as additional discoveries are made. Although we present human evolution in a somewhat linear fashion, from ancient hominins to anatomically and behaviorally modern humans, the human family tree is not a single trunk; rather, it has several branches (FIG. 22-9). Perhaps it is most useful to think of the known hominin fossils as a sampling of human evolution instead of a continuous sequence.

(a) The ape skull has a pronounced supraorbital ridge.

(b) The human skull is flatter in the front and has a pronounced chin. The human brain, particularly the cerebrum (purple), is larger than that of an ape, and the human jaw is structured so that the teeth are arranged in a U shape. Human canines and incisors are also smaller than those of apes.

Figure 22-8 Gorilla and human heads

Homo sapiens is the only species of hominin in existence today, but more than one hominin species coexisted at any given time for most of the past 4 million years. In addition, do not make the mistake of thinking that your smaller-brained ancestors were inferior to yourself. Ancestral hominins were evolutionarily successful in that they were well adapted to their environment and survived for millions of years.

The earliest hominins may have lived 6 mya to 7 mya

Hominin evolution began in Africa. Although most hominin fossils have been discovered in Ethiopia and Kenya, French paleontologist Michel Brunet and an international team made a stunning discovery in 2002 in a dry lake bed in Chad, which is in central Africa. The fossil, which has been reliably dated at 6 million to 7 million years old, may be the earliest known hominin. Viewed from the back, the skull of *Sahelanthropus*, with its small braincase, resembles that of a chimpanzee. However, viewed from the front, the face and teeth have many characteristics of larger-brained human ancestors. Most paleoanthropologists place *Sahelanthropus* close to the base of the human family tree, that is, close to when genetic analyses suggest that the last common ancestor of hominins and chimpanzees existed. The discovery of *Sahelanthropus* is important in its own right, but it is also significant because it shows that early hominins exhibited more variation and lived over a larger area of Africa than had been originally hypothesized.

Orrorin, discovered in 2000 in Kenya, may also represent one of the earliest known hominins. The sediments in which fossils of *Orrorin* were found have been reliably dated at 6 million years old. In 2008, researchers studying the fossil leg bones of *Orrorin* concluded that it walked upright and was bipedal.

As with many aspects of human evolution, scientists have differing interpretations of *Sahelanthropus* and *Orrorin*. For example, some paleoanthropologists hypothesize that *Sahelanthropus* was a forerunner of modern apes, specifically the gorilla, and not one of the earliest ancestors of humans. Other researchers think the similar features of *Sahelanthropus*, *Orrorin*, and *Ardipithecus* (discussed in the next section) fossils mean that they are all members of the same genus, *Ardipithecus*. This point remains controversial, largely because there are currently no skeletal bones (leg, pelvis, and foot bones) to indicate if *Sahelanthropus* walked upright, a hallmark characteristic of hominins. (A 2005 reconstruction of the skull has features that strongly suggest *Sahelanthropus* was bipedal.) Future fossil discoveries and additional analyses of existing fossils should help clarify the evolutionary relationships among *Sahelanthropus*, *Orrorin*, and *Ardipithecus*.

Ardipithecus, *Australopithecus*, and *Paranthropus* are australopithecines, or “southern man apes”

After *Sahelanthropus* and *Orrorin*, the next-oldest hominin belongs to the genus *Ardipithecus*, which lived in eastern Africa between 4 mya and 6 mya. Although not as primitive

Key Point

Paleoanthropologists do not completely agree about certain specific details of the human family tree and hold many possible interpretations of classification lines of descent.

Figure 22-9 One interpretation of human evolution

Please refer to this diagram as you read through Section 22.3. This interpretation, compiled by the author from multiple sources, will likely change as new evidence comes to light.

CONNECT If you were to add *Homo floresiensis* and the Denisovans to this chart, where would you place them? Justify your answers.

as *Sahelanthropus*, *Ardipithecus* is an **australopithecine** that is close to the “root” of the human family tree. The shape of the toe bones suggests that *Ardipithecus* walked upright.

Two species of *Ardipithecus* have been described. The canine teeth of the earliest species, *Ar. kadabba*, have certain primitive features similar to those of *Sahelanthropus* and *Orrorin*. The specific epithet *kadabba* comes from Afar words meaning “basal family ancestor.” *Ardipithecus ramidus* appeared about 4.8 mya. A remarkably complete fossil of a female *Ar. ramidus*, nicknamed Ardi, was described in a series of scientific papers in 2009. Based on details of her anatomy, Ardi has been described as a “facultative biped,” capable of walking upright but also able to climb.

Ardipithecus gave rise to *Australopithecus*, a genus that includes several species that lived between 4 mya and 1 mya. Both *Ardipithecus* and *Australopithecus* had longer arms, shorter legs, and smaller brains relative to those of modern humans.

Hominins that existed between 4.2 mya and 3.9 mya are assigned to the species *Australopithecus anamensis*, first named by paleoanthropologist Meave Leakey and her co-workers in 1995 from fossils discovered in eastern Africa.

This hominin species, which has a mixture of apelike and humanlike features, presumably evolved from *Ardipithecus ramidus*. A comparison of male and female *Australopithecus anamensis* body sizes and canine teeth reveals **sexual dimorphism**, marked phenotypic differences between the two sexes of the same species. (The modern-day gorilla is sexually dimorphic.) The back teeth and jaws of *Au. anamensis* are larger than those of modern chimpanzees, whereas the front teeth are smaller and more like those of later hominins. A fossil leg bone, the tibia, indicates that *Au. anamensis* had an upright posture and was bipedal, although it also may have foraged in the trees. Thus, bipedalism occurred early in human evolution and appears to have been the first human adaptation.

Australopithecus afarensis, another primitive hominin, probably evolved directly from *Au. anamensis*. Many fossils of *Au. afarensis* skeletal remains have been discovered in Africa, including a remarkably complete 3.2-million-year-old skeleton, nicknamed Lucy, found in Ethiopia in 1974 by a team led by U.S. paleoanthropologist Donald Johanson (FIG. 22-10). In 1978, British paleoanthropologist Mary Leakey and her co-workers discovered beautifully preserved fossil footprints of three *Au. afarensis* individuals who walked more than

Lionel Brey/Science Source

Figure 22-10 *Australopithecus afarensis*

This artist's rendition of a female australopithecine and child is based on the fossils of Lucy, discovered in 1974.

3.6 mya. In 1994, paleoanthropologists found the first adult skull of *Au. afarensis*. The skull, characterized by a relatively small brain, pronounced supraorbital ridges, a jutting jaw, and large canine teeth, is an estimated 3 million years old. It is probable that *Au. afarensis* did not construct tools or make fires because no evidence of tools or fire has been found at fossil sites. In 2016 an analysis of Lucy's skeleton provided evidence that she died due to injuries sustained in a fall from a great height. This finding has been taken as evidence that *Au. afarensis* had an arboreal existence.

Many paleoanthropologists think that *Au. afarensis* gave rise to several australopithecine species, including *Australopithecus africanus*, which may have appeared as early as 3 mya. The first *Au. africanus* fossil was discovered in South Africa in 1924, and since then hundreds have been found. This hominin walked erect and possessed hands and teeth that were distinctly humanlike. Given the characteristics of the teeth, paleoanthropologists think that *Au. africanus* ate both plants and animals. Like *Au. afarensis*, it had a small brain, more like that of its primate ancestors than of present-day humans.

In 2010 and 2013, a series of papers in the journal *Science* described *Australopithecus sediba* based on studies of the well-preserved partial skeletons of an adult female and a young boy found in South Africa. Dated at 1.95 mya, these fossils exhibit a mixture of apelike and humanlike features. Like apes, they

have small brains, long arms, and, in the female, a small birth canal. However, among their humanlike features are long legs, a pelvis consistent with bipedal posture, and long, opposable thumbs. Most perplexing of all, they have apelike feet, but their ankle joints are like those of humans. Many scientists think that *Au. sediba* was probably a descendant of *Au. africanus*, but there is considerable disagreement on other issues. Was *Au. sediba* part of the line leading to humans or an evolutionary dead end?

Three australopithecine species (*Paranthropus robustus* from South Africa and *P. aethiopicus* and *P. boisei*, both from East Africa) were larger than *Au. africanus* and had extremely large molars, very powerful jaws, relatively small brains, and bony skull crests. Most females lacked the skull crests and had substantially smaller jaws than *Au. africanus*, another example of sexual dimorphism in early hominins. The teeth and jaws suggest a diet, perhaps of tough roots, nuts, and seeds, that would require powerful grinding. (However, a 2008 study of fossil teeth of *P. boisei* found that the wear on the teeth suggested a softer diet, such as fruits. *P. boisei* apparently ate soft food during times of plenty but could eat hard items during food shortages.) These so-called *robust australopithecines* may or may not be closely related but are generally thought to represent evolutionary offshoots, or side branches, of human evolution. The first robust australopithecine, *P. aethiopicus*, appeared about 2.5 mya.

The actual number of australopithecine species for which fossil evidence has been found is under debate. In some cases, differences in the relatively few skeletal fragments could indicate either variation among individuals within a species or evidence of separate species.

Homo habilis* is considered the oldest member of genus *Homo

The first hominin to have enough uniquely human features to be placed in genus *Homo*, the same genus as modern humans, is *Homo habilis*. It was first discovered in the early 1960s at Olduvai Gorge in Tanzania. Since then, paleoanthropologists have discovered other fossils of *H. habilis* in eastern and southern Africa. *Homo habilis* was a small hominin with a larger brain and smaller premolars and molars than those of the australopithecines. This hominin appeared approximately 2.5 mya and persisted for about 900,000 years. Fossils of *H. habilis* have been found in numerous areas in Africa. These sites contain primitive tools, stones that had been chipped, cracked, or hammered to make sharp edges for cutting or scraping. *Oldowan* pebble choppers and flakes, for example, were probably used to cut through animal hides to obtain meat and to break bones for their nutritious marrow.

The relationship between the australopithecines and *H. habilis* is not clear. Using physical characteristics of their fossilized skeletons as evidence, many paleoanthropologists have inferred that the australopithecines were ancestors of *H. habilis*. Some researchers do not think that *H. habilis* belongs in the genus *Homo*, and they suggest that it should be reclassified as *Australopithecus habilis*. The discovery of *Au. sediba*, described in the previous section, has added fuel to this debate.

The debate has become even more lively since 2015, following reports of the 2013 discovery of 1550 specimens from at least 15 individuals in the Rising Star cave system in South Africa. As with *Au. sediba*, the bones of *Homo naledi* exhibit a mixture of modern and primitive characteristics. These include small brains, upper limbs adapted for climbing and tool use, and lower limbs adapted for upright posture. Many questions arose: Was *H. naledi* actually an australopithecine? Did it evolve at the base of the *Homo* family tree, or did it exist much later? After subjecting the specimens to six methods of dating, scientists reported in 2017 that the remains are between 236,000 and 335,000 years old. Their findings support the hypothesis that *H. naledi* was not a direct ancestor of modern humans, but was instead a species that survived from a much earlier time and lived alongside humans in Africa.

Homo ergaster* may have arisen from *H. habilis

Initially, fossils that are now classified as *Homo ergaster* were considered by some scientists as early *H. erectus* (discussed in next section). With the discovery of additional fossils, however, many scientists hypothesized that the fossils classified as *H. erectus* really represent two species, ***Homo ergaster***, an earlier African species, and *H. erectus*, a later eastern Asian offshoot. The best-known fossils of *H. ergaster*, which existed from 2.0 mya to 1.4 mya, come from the Lake Turkana region in Kenya. Researchers who support the split speculate that *H. ergaster* may be the direct ancestor of later humans, whereas *H. erectus* may be an evolutionary dead end.

Homo erectus* probably evolved from *H. ergaster

Investigators found the first fossil evidence of ***Homo erectus*** in Indonesia in the 1890s. Since then, researchers have found numerous fossils of *H. erectus* throughout Africa and Asia. Paleoanthropologists think that *H. erectus* originated in Africa about 1.7 mya and then spread to Europe and Asia. Peking man and Java man, discovered in Asia, were later examples of *H. erectus*, which existed until at least 200,000 years ago; some populations of *H. erectus* may have persisted more recently.

Homo erectus was taller than *H. habilis*. Its brain, which was larger than that of *H. habilis*, got progressively larger during the course of its evolution. Its skull, although larger, did not possess totally modern features, retaining the heavy supraorbital ridge and projecting face that are more characteristic of its ape ancestors (FIG. 22-11). *Homo erectus* is the first hominin to have fewer differences between the sexes.

The increased intelligence associated with a larger brain enabled these early humans to make more advanced stone tools, known as *Acheulean* tools, including hand axes and other implements that scientists have interpreted as choppers, borers, and scrapers (FIG. 22-12). Their intelligence also allowed these humans to survive in cold areas. *Homo erectus* obtained food by hunting or scavenging and may have worn

Figure 22-11 *Homo erectus* skull from China

The reconstructed parts are white. Note the receding forehead, pronounced supraorbital ridge, and projecting face and jaws.

clothing, built fires, and lived in caves or shelters. Evidence of weapons (spears) has been unearthed at *H. erectus* sites in Europe. (For the remarkable story of an evolutionary offshoot from *H. erectus*, see *Inquiring About: The Smallest Humans*.)

Archaic humans date from about 1.2 mya to 200,000 years ago

Archaic humans are regionally diverse descendants of *H. ergaster* that lived in Africa, Asia, and Europe from about 1.2 mya to 200,000 years ago. The brains of archaic humans were essentially the same size as our brains, although their skulls retained some ancestral characters. Populations of archaic humans had rich and varied cultures (learned traditions) that included making many kinds of tools and objects with symbolic and ceremonial meaning.

Some researchers classify the oldest archaic human fossils discovered in Europe (in Spain) as ***Homo antecessor***. *Homo antecessor* existed from about 1.2 mya to 800,000 years ago. Sites where *H. antecessor* fossils have been found show numerous cuts on human bones that suggest that these early humans practiced cannibalism.

Homo heidelbergensis, which appeared about 600,000 years ago and existed until about 300,000 years ago, may have descended from *H. antecessor*. Fossils of *H. heidelbergensis*

Javier Trueba/Madrid Scientific Films/Science Source

Figure 22-12 Acheulean tool

This stone tool is a typical Acheulean tool. It was made about 800,000 years ago by striking both sides of the biface (shown) to make a teardrop shape. The tool was found with other fossils and tools in Gran Dolina, Sierra de Atapuerca, Spain.

were first discovered in Germany about one hundred years ago. This extinct hominin had a larger brain—similar in size to that of modern humans—than *H. ergaster* or *H. antecessor*.

Some scientists do not recognize *H. antecessor* and suggest that *H. antecessor* fossils should be classified as *H. heidelbergensis*. Classification of *H. heidelbergensis* is also controversial because many (but not all) of the scientists studying its fossil remains think that both Neandertals and modern humans descended from it.

Neandertals appeared approximately 250,000 years ago

Fossils of **Neandertals** were first discovered in the Neander Valley in Germany.¹ They lived throughout Europe and western Asia from about 250,000 to 28,000 years ago. Although at one time many scientists considered Neandertals as a subspecies of *H. sapiens*, increasing evidence suggests that Neandertals were a separate species from modern humans, carrying the name *Homo neanderthalensis*.

¹ *Neandertal* was formerly spelled *Neanderthal*. The silent h has been dropped in modern German but not in the scientific name.

These early humans had short, sturdy builds. Their faces projected slightly, their chins and foreheads receded, they had heavy supraorbital ridges and jawbones, and their brains and front teeth were larger than those of modern humans. They had large nasal cavities and receding cheekbones. Scientists have suggested that the large noses provided larger surface areas in Neandertal sinuses, enabling them to better warm the cold air of Ice Age Eurasia as inhaled air traveled through the head to the lungs.

Neandertal tools, known as *Mousterian* tools, were more sophisticated than those of *H. erectus* (FIG. 22-13). Studies of Neandertal sites indicate that Neandertals hunted large animals. The existence of skeletons of elderly Neandertals and of some with healed fractures may demonstrate that Neandertals cared for the aged and the sick, an indication of advanced social cooperation. They apparently had rituals, possibly of religious significance, made jewelry, and sometimes buried their dead.

The disappearance of the Neandertals about 28,000 years ago is a mystery that has sparked debate among paleoanthropologists. Groups of *H. sapiens* with more modern features coexisted with the Neandertals for several thousand years. Perhaps the other humans outcompeted or exterminated the Neandertals, leading to their extinction. It is also possible that the Neandertals interbred with these humans, diluting their features beyond recognition.

Dirk Wiersma/Science Source

Figure 22-13 Mousterian tool

Mousterian tools are named after a Neandertal site in Le Moustier, France. Mousterian tools include a variety of skillfully made stone tools; this tool, with its sharp edges, was probably used to scrape hides and/or to form the point of a spear. Although Neandertals had spears, they did not develop bows and arrows and so had to get close to their prey when hunting.

Inquiring About

The Smallest Humans

Evolutionarily speaking, what are “hobbits”? In 2004, paleoanthropologists reported a startling discovery of fossils of seven humans in a cave on the Indonesian island of Flores. The finding was completely unexpected because the fossil bones and teeth were from adult humans that were about 1 m (about 3 ft) tall.

The tiny humans, which have been dubbed “hobbits” by the media, may represent a new species, *Homo floresiensis*. Although these hominins had small, ape-sized brains, sophisticated stone tools, fireplaces, and charred bones found with the fossils indicate that *H. floresiensis* was capable of complex thinking and activities. The charred bones were primarily from pygmy elephants (*Stegodon*) and Flores giant rats (*Papagomys*), and they provide clues about the food that *H. floresiensis* hunted and killed (see figure).

Detailed studies of the *H. floresiensis* braincase, published in 2005, revealed that it was similar in many ways to the larger brain of *H. erectus*, which is known to have lived on nearby islands. Many researchers have concluded from this and other evidence that *H. floresiensis* was an evolutionary offshoot of *H. erectus*.

Why was *H. floresiensis* so small? Biologists have often observed two evolutionary

trends of mammals living on remote islands: large mammals tend to evolve into much smaller species, and small mammals tend to evolve into much larger species. It is not unreasonable to assume that the small population of *H. erectus* ancestors that colonized Flores, perhaps by rafting to the island on a log, underwent evolutionary dwarfing over the thousands of years that they were isolated on Flores. (If *H. erectus* had been a frequent visitor to Flores, gene flow between the indigenous population and the visitors would have prevented the indigenous population from becoming measurably smaller.)

Not everyone agrees with the hypothesis that *H. floresiensis* is a separate species of tiny humans. Some researchers have suggested that the fossils are from *H. sapiens* individuals suffering from a rare genetic defect (microcephaly) that causes small brains and bodies. This hypothesis has become less tenable as the cave fossils have been dated to at least 60,000 years ago, a time when no modern humans lived in that area. In 2014 researchers excavating at a different location on Flores found additional fossils: a fragment of a jaw and a skull, as well as adult and baby teeth. These individuals have been calculated to have been about 20% smaller than those whose remains were found in the cave. These fossils have been

dated to 700,000 years ago, a finding consistent with the idea that *H. floresiensis* was a species with a very long history on Flores.

Peter Schouten

Increasingly sophisticated methods of DNA analysis contribute useful data for such controversies. Studies of nuclear DNA of Neandertals have indicated that between 1% and 5% of Neandertal DNA is shared with modern human populations outside of Africa, supporting the hypothesis that some human–Neandertal interbreeding did occur. Interestingly, Neandertal Y chromosome DNA is absent in modern human populations, indicating that there was a possible genetic incompatibility between *H. sapiens* mothers and hybrid male offspring.

In 2012, scientists reported on the genome of a Neandertal relative. DNA was extracted from fossil remains of a young girl excavated from Denisova Cave in Siberia. The fossils, consisting of a finger bone and two teeth, are from sediments that have been dated to 50,000 years. Additional human fossils from the cave are at least 110,000 years old, and possibly older. Scientists consider these archaic humans, provisionally known as the Denisovans, a sister group to the Neandertals. Again there is evidence for inbreeding between archaic humans and *H. sapiens*. Denisovan DNA sequences ranging from traces to as much as 3% have been found in some present-day Asian and Oceanic island populations.

Scientists have reached a near consensus on the origin of modern *H. sapiens*

Homo sapiens with a mixture of primitive and modern features existed in Africa by about 300,000 years ago. As anatomically modern humans later dispersed around the world, they displaced other hominins such as *H. erectus* and *H. neanderthalensis*. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining, excluding small, isolated populations.

Both recent fossil finds and extensive molecular analyses have promoted the **(recent) out-of-Africa model** (also called *Recent Africa Origin*, or RAO) as the main explanation for the origin of modern humans living around the world. New data include the discovery of the earliest fossilized remains of modern *H. sapiens* in Africa and analyses of DNA from mitochondria, the Y chromosome, and autosomes. In 2005, fossils of the earliest known modern *H. sapiens* were reliably dated at 195,000 years old; these fossils were found in southern Ethiopia. No *H. sapiens* fossils of comparable age have been found in Europe or Asia. The earliest fossils of anatomically modern *H. sapiens* in Europe and most parts

Figure 22-14 The path of human migrations, based on Y chromosome data

Homo sapiens originated in Africa and migrated from there throughout the world.

of Asia date to 45,000 to 40,000 years ago. One exception is in Israel, where *H. sapiens* fossils have been dated at 100,000 years before present.

Molecular anthropology, the comparison of biological molecules from present-day individuals of regional human populations, provides clues that help scientists unravel the origin of modern humans and trace human migrations. A series of genetic studies of mtDNA, the Y chromosome, and autosomal DNA has strengthened the case for Africa as the birthplace of modern humans (**FIG. 22-14**). These studies provide detailed comparisons of DNA in present-day populations around the world as well as ancient DNA extracted from Neandertal and early *H. sapiens* remains.

22.4 Cultural Change

LEARNING OBJECTIVE

- 8** What are the generally recognized cultural stages that human populations have experienced?

Genetically speaking, humans are not very different from other primates. At the level of our DNA sequences, we are roughly 98% identical to gorillas and 99% identical to chimpanzees. Our relatively few genetic differences, however, give rise to several important distinguishing features, such as greater intelligence and the ability to capitalize on it by transmitting knowledge from one generation to the next. Human culture is not inherited in the biological sense but instead is learned, largely through the medium of language.² It is dynamic and is modified as people obtain new knowledge. Human culture is generally divided into three stages: (1) the development of hunter-gatherer societies, (2) the development of agriculture, and (3) the Industrial Revolution.

Early humans were hunters and gatherers who relied on what was available in their immediate environment. They

² Humans are not the only animals to have culture. Chimpanzees have primitive cultures that include tool-using techniques, hunting methods, and social behaviors that vary from one population to another. These cultural traditions are passed to the next generation by teaching and imitation; see Figure 1-17.

were nomadic, and as the resources in a given area were exhausted or as the population increased, they migrated to a different area. These societies required a division of labor and the ability to make tools and weapons, which were needed to kill game, scrape hides, dig up roots and tubers, and cook food. Although scientists are not certain when hunting was incorporated into human society, they do know that it declined in importance approximately 15,000 years ago. This decline may have been due to a decrease in the abundance of large animals, triggered in part by overhunting. A few isolated groups of hunter-gatherer societies, such as the Inuit of the northern polar region and the Mbuti of Africa, survived into the 21st century.

Development of agriculture resulted in a more dependable food supply

Evidence that humans had begun to cultivate crops approximately 10,000 years ago includes the presence of agricultural tools and plant material at archaeological sites. Agriculture resulted in a more dependable food supply. Archaeological evidence suggests that agriculture arose in several steps. Although there is variation from one site to another, plant cultivation, in combination with hunting, usually occurred first. Animal domestication generally followed later, although in some areas, such as Australia, early humans did not domesticate animals.

Agriculture, in turn, often led to more permanent dwellings because considerable time was invested in growing crops in one area. Villages and cities often grew up around the farmlands, but the connection between agriculture and the establishment of villages and towns is complicated by certain discoveries. For example, Abu Hureyra in Syria was a village founded *before* agriculture arose. The villagers subsisted on the rich plant life of the area and the migrating herds of gazelle. Once people turned to agriculture, however, they seldom went back to hunting and gathering to obtain food.

Other advances in agriculture include the domestication of animals, which people kept to supply food, milk, and hides. Archaeological evidence indicates that wild goats and sheep were probably the first animals to be domesticated in southwestern Turkey, northern Iraq, and Iran. In the Old World, people also used animals to prepare fields for planting. Another major advance in agriculture was irrigation, which began more than 5000 years ago in Egypt.

Producing food agriculturally was more time-consuming than hunting and gathering, but it was also more productive. In hunter-gatherer societies, everyone shares the responsibility for obtaining food, but in agricultural societies, fewer people are needed to provide food for everyone. Thus, agriculture freed some people to pursue other endeavors, including religion, art, and various crafts.

Human culture has had a profound effect on the biosphere

Human culture has had far-reaching effects on both human society and on other organisms. The Industrial Revolution, which began in the 18th century, drew populations to concentrate in urban areas near centers of manufacturing. Advances in agriculture encouraged urbanization because fewer and fewer people were needed in rural areas to produce food for everyone. The spread of industrialization increased the demand for natural resources to supply the raw materials for industry. Chapter 53 discusses increases in human population size, and Chapter 57 investigates the effect of humans on the environment.

CHECKPOINT 22.4

- **CONNECT** Describe some of the transitions from hunter-gatherer societies to agricultural societies to the Industrial Revolution. Have all societies gone through these stages in this order?

Summary: Focus on Learning Objectives

22.1 Primate Adaptations (page 462)

1 Describe the structural adaptations that primates have for life in treetops.

- **Primates** are *placental mammals* that arose from small, arboreal (tree-dwelling), shrewlike mammals. Primates possess five grasping digits, including an **opposable thumb** or toe; long, slender limbs that move freely at the hips and shoulders; and eyes located in front of the head.

22.2 Primate Classification (page 462)

2 List the three suborders of primates and give representative examples of each.

- Primates are divided into three suborders. The suborder Prosimii includes lemurs, galagos, and lorises. The suborder Tarsiiformes includes tarsiers. The suborder Anthropoidea includes anthropoids: monkeys, apes, and humans.

3 Distinguish among anthropoids, hominoids, and hominins.

- **Anthropoids** include monkeys, apes, and humans. Early anthropoids branched into two groups: New World monkeys and Old World monkeys.
- **Hominoids** include apes and humans. Hominoids arose from the Old World monkey lineage. There are four modern genera of apes: gibbons, orangutans, gorillas, and chimpanzees.
- The **hominin** line consists of humans and their ancestors.

22.3 Hominin Evolution (page 467)

4 Describe skeletal and skull differences between apes and hominins.

- Unlike ape skeletons, hominin skeletons have adaptations that reflect the ability to stand erect and walk on two feet. These adaptations include a complex curvature of the spine; a shorter, broader pelvis; repositioning of the **foramen magnum** to the base of the skull; and a first toe that is aligned with the other toes.
- The human skull lacks a pronounced **supraorbital ridge**, is flatter than ape skulls in the front, and has a pronounced chin. The human brain is larger than ape brains, and the jaw is structured so that the teeth are arranged in a U shape.

5 Briefly describe the following early hominins: *Orrorin*, *Ardipithecus*, *Australopithecus anamensis*, *Au. afarensis*, *Au. africanus*, and *Au. sediba*.

- *Orrorin* is an early hominin that arose about 6 mya. Researchers studying the fossil leg bones of *Orrorin* think that it walked upright and was **bipedal** (walked on two feet).

- *Ardipithecus*, *Australopithecus*, and *Paranthropus* species are often referred to as **australopithecines**. Australopithecines were bipedal, a hominin feature. The first *Ardipithecus* species, *Ar. kadabba*, appeared about 5.8 mya. ***Ardipithecus ramidus***, which appeared about 4.8 mya, may have given rise to ***Australopithecus anamensis***, which in turn probably gave rise to another primitive hominin, ***Australopithecus afarensis***. Many paleoanthropologists think that *Au. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus***, *Paranthropus* spp., and possibly *Homo habilis*. ***Australopithecus sediba*** may have descended from *Au. africanus*.

6 Distinguish among the following members of genus *Homo*: *H. habilis*, *H. ergaster*, *H. erectus*, *H. antecessor*, *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens*.

- ***Homo habilis*** was the earliest known hominin with some of the human features lacking in the australopithecines, including a slightly larger brain. *Homo habilis* fashioned crude tools from stone.
- The best-known fossils of ***H. ergaster***, which existed from 2.0 mya to 1.4 mya, come from Kenya. *Homo ergaster* may be the direct ancestor of later humans.
- ***Homo erectus*** had a larger brain than *H. habilis*; made more sophisticated tools; and may have worn clothing, built fires, and lived in caves or shelters. *Homo erectus*, which is probably a later Asian offshoot of *H. ergaster*, appears to be an evolutionary dead end.
- Archaic humans are regionally diverse descendants of *H. ergaster* that lived in Africa, Asia, and Europe from about 1.2 mya to 200,000 years ago. The brains of archaic humans were essentially the same size as our brains, although their skulls retained some ancestral characters, and they had rich and varied cultures.
- Some researchers classify the oldest archaic human fossils discovered in Europe (in Spain) as *Homo antecessor*. ***Homo antecessor*** existed from about 1.2 mya to 800,000 years ago.
- ***Homo heidelbergensis***, which appeared about 600,000 years ago and existed until about 300,000 years ago, may have descended from *H. antecessor*. This extinct hominin had a larger brain—similar in size to that of modern humans—than either *H. ergaster* or *H. antecessor*. Many scientists studying *H. heidelbergensis* think that both Neandertals and modern humans descended from it.
- **Neandertals** lived from about 250,000 to 28,000 years ago. Neandertals had short, sturdy builds; receding chins and foreheads; heavy supraorbital ridges and jawbones; larger front teeth; and nasal cavities with unusual triangular bony projections. Many scientists think that Neandertals were a separate species, ***Homo neanderthalensis***.
- ***Homo sapiens*** with a mixture of primitive and modern features existed in Africa by about 300,000 years ago. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining, excluding small, isolated populations.

7 Discuss the origin of modern humans.

- Recent fossil finds and extensive molecular analyses have promoted the **(recent) out-of-Africa model** as the main explanation for the origin of modern humans living around the world. New data include the discovery of the earliest fossilized remains of modern *H. sapiens* in Africa and analyses of DNA from mitochondria, the Y chromosome, and autosomes.

Test Your Understanding

Know and Comprehend

- The first primates evolved from (a) shrewlike monotremes (b) therapsids (c) shrewlike placental mammals (d) tarsiers (e) shrewlike marsupials
- The anthropoids are more closely related to _____ than to _____. (a) tarsiers; lemurs (b) lemurs; monkeys (c) tree shrews; tarsiers (d) lemurs; tarsiers (e) tree shrews; monkeys
- With what group do hominoids share the most recent common ancestor? (a) Old World monkeys (b) New World monkeys (c) tarsiers (d) lemurs (e) lorises and galagos
- The _____ in humans is centered at the base of the skull, positioning the head for erect walking. (a) supraorbital ridge (b) foramen magnum (c) pelvis (d) bony skull crest (e) femur
- Scientists collectively call humans and their *immediate* ancestors (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominins
- The earliest hominin that most paleoanthropologists place in genus *Homo* is (a) *H. habilis* (b) *H. ergaster* (c) *H. erectus* (d) *H. heidelbergensis* (e) *H. neanderthalensis*
- Some scientists now think that fossils identified as *Homo erectus* represent which two different species? (a) *H. habilis* and *H. erectus* (b) *H. ergaster* and *H. erectus* (c) *H. heidelbergensis* and *H. ergaster* (d) *H. neanderthalensis* and *H. erectus* (e) *H. neanderthalensis* and *H. sapiens*
- Archaic humans appeared as early as _____ years ago. (a) 5 million (b) 1.2 million (c) 250,000 (d) 100,000 (e) 5000
- _____ were an early group of humans with short, sturdy builds and heavy supraorbital ridges that lived throughout Europe and western Asia from about 250,000 to 28,000 years ago. (a) australopithecines (b) dryopithecines (c) archaic humans (d) Neandertals (e) Denisovans
- The modern human skull *lacks* (a) small canines (b) a foramen magnum centered in the base of the skull (c) pronounced supraorbital ridges (d) a U-shaped arrangement of teeth on the jaw (e) a large cranium (braincase)
- The comparison of genetic material from individuals of regional populations of humans, used to help unravel the origin and migration of modern humans, is known as (a) paleoarchaeology (b) cultural anthropology (c) molecular anthropology (d) cytogenetics (e) genetic dimorphism

Apply and Analyze

- Place the following hominins in chronological order of appearance in the fossil record, beginning with the earliest: 1. *H. ergaster* 2. *H. sapiens* 3. *H. neanderthalensis* 4. *H. erectus* (a) 1, 4, 2, 3 (b) 4, 1, 2, 3 (c) 4, 1, 3, 2 (d) 3, 1, 4, 2 (e) 1, 4, 3, 2

22.4 Cultural Change (page 474)

8 What are the generally recognized cultural stages that human populations have experienced?

- Large human brain size makes possible the transmission of knowledge from one generation to the next. Significant advances in human culture were the transition from a hunter-gatherer way of life to the development of agriculture and the Industrial Revolution.

Evaluate and Synthesize

- If you were evaluating whether other early humans exterminated the Neandertals, what kinds of archaeological evidence might you look for?
- The remains of *H. sapiens* have been found in southern Europe alongside reindeer bones, but reindeer currently exist only in northern Europe and Asia. Explain the apparent discrepancy.
- EVOLUTION LINK** What was the common ancestor of chimpanzees and humans: a chimpanzee, a human, or neither? Explain your answer.
- EVOLUTION LINK** Some scientists say that modern medicine and better sanitation are slowing down or altering the course of human evolution in highly developed countries today. As a result, evolution in humans today has gone from survival of the fittest to survival of almost everyone. Do you think that this idea is valid? Why or why not?
- INTERPRET DATA** Using the information in Figure 22-9, draw a simple cladogram that represents a reasonable hypothesis of human evolution at the genus level. (*Hint*: Your diagram will have three branches.)
- INTERPRET DATA** The four chromosomes depicted here are Y chromosomes from men in different parts of the world. The *light purple bands* represent specific genes that are identical in all four men. The *red bands* represent genetic mutations (M) that appeared at different times; M168 appeared about 50,000 years ago, M9 about 40,000 years ago, and M3 about 10,000 years ago. Based on what you have learned in this chapter, identify the geographic source of men carrying each of these chromosomes: African, Eurasian, Amerindian, and first migrants out of Africa. (You may wish to refer back to Figure 22-14.)

23 Understanding Diversity: Systematics

KEY CONCEPTS

- 23.1** Traditionally, biologists have named organisms using a binomial system (in which each species has a genus name followed by a specific epithet) and have classified organisms in taxonomic categories arranged in a hierarchy from most inclusive (domain) to least inclusive (species).
- 23.2** Based on current knowledge, the three main branches of the tree of life are the three domains: Bacteria, Archaea, and Eukarya.
- 23.3** Modern systematics seeks to reconstruct phylogeny (evolutionary history of a group of organisms) based on common ancestry inferred from shared characters (characteristics)—including structural, developmental, behavioral, and molecular similarities—as well as from fossil evidence.
- 23.4** Cladograms (a type of phylogenetic tree) are diagrams of hypothetical evolutionary relationships; they are constructed by analyzing shared derived characters.
- 23.5** Knowledge of modern systematics informs research in many other areas, including ecology and medicine.

PHOTO: A recently discovered peacock spider (*Maratus lobatus*). Peacock spiders are known for their elaborate courtship displays.
Jürgen Otto

The total number of living eukaryotic species on Earth is estimated to be between about 8.7 million and 100 million, but only about 1.9 million species have been described. Biologists estimate that to date they have identified less than 15% of terrestrial species and less than 10% of marine species. Many regions on our planet have not yet been carefully inventoried, including the forest canopy, soil, and the deep regions of the ocean.

Biologists discover thousands of new species each year. For example, Sydney biologist Jürgen Otto has identified several new species of peacock spider during the past few years (see photograph). Native to Australia, these brightly colored arachnids are very small, with an adult body length of only about 5 mm.

The variety of living organisms and the ecosystems they are part of are referred to as **biological diversity**, or **biodiversity**. The totality of life on Earth represents our biological heritage, and the quality of life for all organisms depends on the health and balance of this worldwide web of life-forms. For example, we depend on organisms to maintain the life-sustaining composition of gases in the atmosphere, form soil, break down wastes, recycle nutrients, and provide food for one another.

We humans exploit many species for economic benefit. One very anthropocentric (human-centered) example of the practical importance of biodiversity is that more than 40% of the prescriptions that pharmacists dispense in the United States derive from living organisms. Investigators continue to learn how to effectively screen organisms for potential drugs. Unfortunately, human activity is seriously reducing biodiversity, and species are becoming extinct faster than researchers can study them. (See the discussion on declining biodiversity in Chapter 57.)

Alarmed by these extinctions, biologists are mobilizing to more rapidly identify new species and to conserve biodiversity. Many biologists agree that describing and classifying all the surviving species of the world should be a major scientific goal of the 21st century. Important steps toward this goal are being taken by international research endeavors. For example, the *Catalogue of Life* is the work of a collaborative international research team that manages a comprehensive global database made available on the Internet. This team categorizes and lists all the world's known species. The *Encyclopedia of Life (EOL)*, a project launched in 2007, is an electronic database that includes a home page for each species. There are currently more than one million pages in this online resource, with information about more than 1.6 million species. Data include alternative names for each organism, classification, habitat, distribution, and diet. The Convention on Biological Diversity is an international treaty committed to reducing the "rate of loss of biodiversity." The 196 countries that make up this convention work to develop strategies for the conservation and sustainable use of Earth's biological diversity.

In this chapter we explore some of the approaches and methods used by biologists to classify organisms and infer their evolutionary history and relationships. (The evolution of species is discussed in Chapter 20.) Information comes from many sources, including fossils, and biogeography as well as homologies in structure, physiology, behavior, and patterns of development. Advances in DNA sequencing have generated huge amounts of data about molecular similarities and differences.

Systematics is the scientific study of the diversity of organisms and their evolutionary relationships. Recall from earlier chapters (e.g., see Chapter 18) that **evolution** is the accumulation of inherited changes within populations over time. *Systematists*, biologists who study systematics, organize information about groups of organisms ranging from a small number of populations to all life on Earth. They generate hypotheses regarding patterns of evolutionary relationships for these groups of organisms. As more sophisticated molecular methods and discovery of new fossils provide new data, old data are reinterpreted. As we gain greater understanding of how organisms are related, we revise the way we classify organisms. We can use the phylogenetic information for naming species as well as for investigating specific hypotheses about directions of evolutionary change and about the particular factors that may have caused certain evolutionary changes.

23.1 Classifying Organisms

LEARNING OBJECTIVES

- 1 State two justifications for the use of scientific names and classifications of organisms.
- 2 Describe the binomial system of naming organisms and arrange the Linnaean categories in hierarchical fashion from most inclusive to least inclusive.

Taxonomy, the science of naming, describing, and classifying organisms, is an important aspect of systematics. In biology the term **classification** means arranging organisms into groups based on similarities that reflect evolutionary relationships among lineages.

For hundreds of years, scientists have realized that certain groups of organisms share many features. Saying something like "Species X is some kind of cat," tells a person that species X falls somewhere between tigers and house cats. It

also suggests that species X has many features shared with other cats, ranging from details of the heart, skin, muscles, and skeleton, to molecular traits like amino acid sequences in particular proteins and nitrogenous base sequences in DNA, and even to complex traits like behaviors and aspects of their physiology.

After the work of Charles Darwin, we came to realize that organisms within such groups share so many traits because they have all inherited those traits from the same ancestor. The living species are "related" via shared ancestors, and the traits they share are *homologous traits* (see Chapter 18). Modern systematists seek to name and classify organisms according to their evolutionary relationships. This work involves some careful investigations as we attempt to determine the patterns of relationships.

Organisms are named using a binomial system

In the mid-18th century, Carolus Linnaeus developed a system of naming organisms to allow scientists to communicate more clearly. We will discuss his contributions to classification in the next section, but here we focus on his idea for naming species.

Before the mid-18th century, each species had a lengthy descriptive name, sometimes consisting of 10 or more Latin words! Linnaeus simplified scientific classification, developing a **binomial system of nomenclature** in which each species is assigned a unique two-part name. The first part of a binomial scientific name is a noun that designates the **genus** (pl., *genera*), and the second part, an adjective modifying that noun, is called the **specific epithet**.

The genus name is always capitalized, whereas the specific epithet is usually not. Both names are underlined or italicized. The genus, or generic, name can be used alone to designate all species in the genus (e.g., the genus *Quercus* includes all oak species). Note that the specific epithet alone is *not* the name of the species. In fact, the same specific epithet can be used as the second name of species in different genera. For example, *Quercus alba* is the scientific species name for the white oak, and *Salix alba* is the species name for the white willow (*alba* comes from a Latin word meaning "white"). Thus, both parts of the name must be used to identify the species accurately. The specific epithet is never used alone; it must always follow the full or abbreviated genus name, such as *Quercus alba* or *Q. alba*.

Scientific names are generally derived from Greek or Latin roots or from Latinized versions of the names of persons, places, or characteristics. For example, the generic name for the bacterium *Escherichia coli* is based on the name of the scientist, Theodor Escherich, who first described it. The specific epithet *coli* reminds us that *E. coli* lives in the colon (large intestine).

Scientific names permit biology to be a truly international science. Even though the common names of an organism may vary in different locations and languages, an organism can be universally identified by its scientific name. A researcher in Puerto Rico knows exactly which organisms were used in a study published by a Russian scientist and therefore can repeat or extend that scientist's experiments using the same species.

Each taxonomic level is more general than the one below it

Linnaeus devised a system for assigning species to a hierarchy of increasingly broader groups. As you move up the hierarchy, each group is more inclusive; that is, it includes the groups below it. When he set up his system, Linnaeus did not have a theory of evolution in mind, nor did he have any idea of the vast number of extant (living) and extinct organisms that would later be discovered. His system nonetheless ended up providing important evidence for evolution, and although some substantial modifications have been necessary, Linnaeus's basic system still forms a framework for much of our modern classifications.

The range of taxonomic categories from species to domain forms a hierarchy (TABLE 23-1 and FIG. 23-1). Closely related species are assigned to the same genus, and closely related genera are grouped in a single **family**. Families are grouped into **orders**, orders into **classes**, classes into **phyla**, phyla into **kingdoms**, and kingdoms into **domains**. A **taxon** (pl., *taxa*) is a formal grouping of organisms at any given level, such as species, genus, or phylum. Today we realize that classifying organisms requires many more classification levels than envisioned by Linnaeus, so between any two categories there could be additional levels. For example, the order Coleoptera (beetles) contains more than 400,000 species, and the class is divided into subclasses, with each subclass containing multiple infraorders, each infraorder containing multiple superfamilies, and each superfamily containing numerous families. Sometimes even these additional levels are not sufficient to categorize important groups.

Another difference between the current classifications and those of Linnaeus is even more substantial. Linnaeus grouped species into particular taxa because they shared certain *features*. In light of our modern understanding of shared ancestry and evolution, we seek to place organisms into particular taxa because they share particular *ancestry*. For example, a modern

biologist would place a species within the taxon Mammalia if all the available evidence showed that the species evolved from the same recent ancestor as the rest of the mammals. This decision would not be based on whether or not members of the species had any one particular feature, like hair or mammary glands.

CHECKPOINT 23.1

- Eating a single “death cap” mushroom can be fatal. The specific epithet of this mushroom is *phalloides*. Its genus name is *Amanita*. Write its scientific name.
- What are the key features of the system of hierarchical classification?
- VISUALIZE** Write a list of the following taxonomic categories in order from most inclusive to least inclusive: genus, order, domain, family, phylum, species, kingdom, class.

23.2 Determining the Major Branches in the Tree of Life

LEARNING OBJECTIVES

- Describe the three domains and argue for and against classifying organisms in these domains. (Compare this approach with using kingdoms as the main rank of classification.)
- Interpret a cladogram, describing the meaning of its specific nodes and branches.
- Differentiate between vertical and horizontal gene transfer and explain their importance in understanding systematics.

The history of taxonomy at the kingdom and domain levels is a good example of the process of science. In this section we will review some highlights of this process.

Systematics is an evolving science

From the time of Aristotle (more than 2300 years ago) to the mid-19th century, biologists divided organisms into two kingdoms: **Plantae** and **Animalia**. After the development of microscopes, it became increasingly obvious that many organisms could not be easily assigned to either the plant or the animal kingdom. For example, the unicellular organism *Euglena* was classified at various times in the plant kingdom and in the animal kingdom, but did not really fit in either kingdom. *Euglena* carries on photosynthesis in the light, but in the dark, it uses its flagellum to move about in search of food (see Fig. 26-5). In 1866, a German biologist, Ernst Haeckel, proposed that a third kingdom, **Protista**, be established to accommodate bacteria and other microorganisms. However, biologists largely ignored this kingdom for about a hundred years.

In 1937, French marine biologist Edouard Chatton suggested the term *procariotique* (“before nucleus”) to describe bacteria and the term *eucariotique* (“true nucleus”) to describe all other cells. The distinction between prokaryotes and eukaryotes is now accepted by biologists as a fundamental evolutionary divergence.

Table 23-1 Classification of Corn	
Domain	Eukarya Organisms that have nuclei and other membrane-enclosed organelles
Kingdom	Plantae Terrestrial, multicellular, photosynthetic organisms
Phylum	Anthophyta Vascular plants with flowers, fruits, and seeds
Class	Monocotyledones Monocots: Flowering plants with one seed leaf (cotyledon) and flower parts in threes
Order	Commelinales Monocots with reduced flower parts, elongated leaves, and dry one-seeded fruits
Family	Poaceae Grasses with hollow stems; fruit is a grain; and abundant endosperm in seed
Genus	Zea Tall annual grass with separate female and male flowers
Species	Zea mays Corn

Figure 23-1 The principal categories used in classification

The domestic cat (*Felis catus*) is classified here to illustrate the hierarchical organization of the Linnaean taxonomic system. Each level is more inclusive than the one below it, meaning that it includes more groups of organisms.

In the 1960s, advances in electron microscopy and biochemical techniques revealed further cell differences that inspired many new proposals for classifying organisms. In 1969, R.H. Whittaker proposed a five-kingdom classification based mainly on cell

structure and the way that organisms derive nutrition from their environment. (Although Whittaker is generally credited, the concept of five kingdoms was actually first proposed in 1949 by T.L. Jahn and F. Jahn in their book *How to Know the Protozoa*.)

Whittaker suggested that the fungi (which include the mushrooms, molds, and yeasts) be removed from the plant kingdom and classified in their own kingdom, **Fungi**. After all, fungi are not photosynthetic. They obtain their nutrition by absorbing nutrients produced by other organisms. Fungi also differ from plants in the composition of their cell walls, their body structures, and their modes of reproduction. Kingdom **Prokaryotae** was established to accommodate the bacteria, which are fundamentally different from all other organisms in that they do not have distinct nuclei and other membranous organelles and do not undergo mitotic division (see Fig. 4-8).

In the late 1970s, Carl Woese (pronounced “woes”) of the University of Illinois and his colleagues began to study the evolutionary relationships among organisms by analyzing genes coding for their ribosomal RNA. Using sequence analysis, Woese used variations in this universal molecule to challenge the long-held view that all prokaryotes were closely related and very similar to one another. The analysis of ribosomal RNA is an important tool used by systematists. Woese showed that there are two fundamentally different groups of prokaryotes, archaea and bacteria. He and his colleagues proposed not only that the archaea are different from the bacteria, but also that the archaea are genealogically more closely related to the eukaryotes than they are to the bacteria.

Woese’s hypothesis gained support in 1996 when Carol J. Bult of the Institute for Genomic Research in Rockville, Maryland, reported in the journal *Science* that she and her colleagues had sequenced the complete genome of a methane-producing archaea, *Methanococcus jannaschii*. When these researchers compared gene sequences with those of two previously sequenced bacteria, they found that fewer than half of the genes matched. Gene sequencing indicates that the archaea have a combination of bacteria-like and eukaryote-like genes. Biologists have identified other important differences between bacteria and archaea. For example, bacteria are characterized by the presence of a compound called peptidoglycan in their cell walls, whereas this compound is not present in archaea. Based on molecular evidence, biologists now divide the prokaryotes into two major groups: *bacteria* and *archaea*.

Kingdom Protista has had an interesting history. Biologists placed *Euglena*, along with other unicellular organisms traditionally referred to as protozoa, in kingdom Protista. At various times, they have also assigned algae (including multicellular forms), water molds, and slime molds to kingdom Protista. Thus, this kingdom became a diverse group of mainly unicellular, mainly aquatic eukaryotic organisms. During the past few years, systematists have established that the protist groups did not descend from one recent common ancestor. As we will discuss in Chapter 26, most biologists have abandoned kingdom Protista (as well as a kingdom classification for plants and animals) and now assign the eukaryotes to five “supergroups” based on molecular data. The word *protist* is currently used as an informal catch-all term.

The three domains form the three main branches of the tree of life

Based on fundamental molecular differences among the bacteria, archaea, and eukaryotes, biologists currently classify organisms in three domains: **Archaea**, **Bacteria**, and **Eukarya** (eukaryotes).

Biologists classify organisms in three major groups called domains.

Figure 23-2 The three domains

This cladogram, a type of evolutionary tree, illustrates the evolutionary relationships among organisms in the three domains. Each branch of the cladogram represents a clade, a group of organisms with a recent common ancestor. Each node (circle) represents the point at which two groups diverged from each other.

PREDICT According to this cladogram, are the Archaea more closely related to the Bacteria or to the Eukarya?

Systematists have inferred that the three domains are the three main branches of the tree of life (**FIG. 23-2**). New data suggest that many core genes of eukaryotes came from archaea. The data support the hypothesis that an archaean was the host cell in the endosymbiosis that led to the evolution of eukaryotes. The hypothesized partnership between archaea and bacteria suggests that all life can be classified into a two-domain system, with eukaryotes as a subgroup. In Chapter 25 we will discuss characters that distinguish these domains. As we will discuss in Chapter 24, the viruses are a special case and are not classified in any of the three domains.

Some biologists are moving away from Linnaean categories

Because modern biologists are interested in having the classifications of living organisms reflect their patterns of relatedness as closely as possible, some of the terminology that has been used for decades is either being put aside or redefined. In addition, our increased ability to investigate the DNA sequences of organisms and improved techniques for analyzing these molecular data are providing many new discoveries regarding the patterns of relatedness among living species. We are in the midst of a time of transition.

Students learning biology during this time of amazing new technology and research need to know that our understanding of many aspects of biology is rapidly changing. Biology textbooks may vary in the classification and terminology they present. For example, biologists are now using the classification system with three domains (Bacteria, Archaea, and Eukarya), with the Eukarya divided into a number of large taxa reflecting shared ancestry. Most biologists no longer recognize the kingdom Protista because many of the organisms within that group are actually more closely related to either plants or animals or fungi than they are to one another (see **TABLE 23-2** and **FIG. 23-3**).

In this edition of *Biology*, we classify organisms using the three domains and also use many of the traditional taxonomic names. We discuss throughout the book instances where the traditional taxonomy is undergoing revision to better reflect our knowledge concerning patterns of common ancestry.

Phylogenetic trees show hypothesized evolutionary relationships

Systematists use **phylogenetic trees** to graphically represent hypothesized evolutionary relationships among organisms

that have a common ancestor. In Figure 23-2 we use a phylogenetic tree to illustrate the relationship of the three domains, and the phylogenetic tree in Figure 23-3 illustrates the main branches that make up each of the three domains. This tree is one of the current versions of the tree of life.

The type of phylogenetic tree we use in this book is called a **cladogram**. Each *branch* in a cladogram represents a **clade**, a group of organisms with a common ancestor. Each branching point, referred to as a *node* (depicted by a circle), represents the divergence, or splitting, of two or more new groups from a common ancestor. Thus, the node represents the *most recent common ancestor* of each clade depicted by the branches. In this way, a cladogram uses the positions of branch points to illustrate the hypothesized evolutionary relationships among taxa. Each of the branches is formed based on evidence in terms of observable traits that are shared by the organisms at the end of the branch but are not found in organisms on other branches. (*Shared derived characters* are discussed in the next section.) These shared characteristics can be indicated by labels or by bars across the branches.

Cladograms are rooted if the most recent common ancestor is known. The *root*, or node at the base of the cladogram, represents the most recent common ancestor of all the clades

Table 23-2 Domains and Kingdoms

Domain	Kingdom	Characteristics	Ecological Role and Comments
	Bacteria	Prokaryotes (lack distinct nuclei and other membranous organelles); unicellular; microscopic; cell walls generally composed of peptidoglycan	Most are decomposers; some parasitic (and pathogenic); some chemosynthetic autotrophs; some photosynthetic; important in recycling nitrogen and other elements; some used in industrial processes.
	Archaea	Prokaryotes; unicellular; microscopic; peptidoglycan absent in cell walls; differ biochemically from bacteria	Decomposers; important in recycling carbon, nitrogen, and other nutrients; methanogens are anaerobes that inhabit sewage, swamps, and animal digestive tracts; extreme halophiles inhabit salty environments; extreme thermophiles inhabit hot, sometimes acidic environments.
	Protists formerly classified in kingdom Protista; now assigned to a number of "supergroups"	Eukaryotes; mainly unicellular or simple multicellular	Protozoa are an important part of zooplankton. Algae are important producers, especially in marine and freshwater ecosystems; important oxygen source. Some protists cause diseases (e.g., malaria).
	Plantae	Eukaryotes; multicellular; photosynthetic; possess multicellular reproductive organs; alternation of generations; cell walls of cellulose	Terrestrial biosphere depends on plants in their role as primary producers; important source of oxygen in Earth's atmosphere.
	Eukarya* Fungi	Eukaryotes; heterotrophic; absorb nutrients; do not photosynthesize; body composed of threadlike hyphae that form tangled masses that infiltrate food or habitat; cell walls of chitin	Decomposers; some parasitic (and pathogenic); some form important symbiotic relationships with plant roots (mycorrhizae) or algae (lichens); some used as food; yeast used in making bread and alcoholic beverages; some used to make industrial chemicals or antibiotics; responsible for much spoilage and crop loss.
	Animalia	Eukaryotes; multicellular heterotrophs; many exhibit tissue differentiation and complex organ systems; most able to move about by muscular contraction; nervous tissue coordinates responses to stimuli	Consumers; some specialized as herbivores, predators, or detritus feeders.

* For another approach to classification of Eukarya, see Figure 23-3.

Figure 23-3 The tree of life, a work in progress

Some major branches of each of the three domains are shown. As new data are analyzed, the relationships of some of the branches will change.

depicted in the tree. We will discuss more about constructing cladograms as we proceed through this chapter.

Although a cladogram depicts the evolutionary relationships of each group through time, the *lengths* of the branches do not tell us *when* a particular species evolved. Other types of phylogenetic trees—for example, *phylograms*—can be constructed to indicate time, or rate of evolution, as well as the relationships among taxa. In a phylogram the length of the branches is proportional to the amount of inferred change in characteristics.

Systematists continue to consider other hypotheses

When we think of how organisms acquire their genes, we think of **vertical gene transfer** in which genes are transmitted from parent to offspring within the same species. We also usually attribute similarities among species in their heritable traits to be the result of shared ancestry, or **homology**. For example, if two species share the same sequence of nitrogenous bases in their DNA for a particular gene, we hypothesize that this sharing is due to the two species having inherited that particular gene from the same ancestor. As biologists have continued to investigate the evolution of genes, they have discovered that in

some cases inheritance can occur outside the parent to offspring pathway.

Throughout the history of life, genes were not only passed down “vertically” from one generation to the next, but were also exchanged “laterally.” In **horizontal gene transfer**, gene swapping takes place between one genome and another within one taxon or between genomes in different taxa. In this process, genes move from one individual to another or from one species to another species in the same generation.

Horizontal gene transfer can occur in several ways, such as by exchange of DNA among different populations or species of bacteria or archaea, or by interbreeding between closely related groups. One way that horizontal gene transfer has occurred in eukaryotes is by **endosymbiosis**, a process in which one organism lives inside the cell of another organism and the two become dependent on each other. Over time, such relationships may result in a complete loss of the

separate identity of the symbionts. In fact, eukaryotic cells most likely evolved from prokaryotic cells that lived symbiotically, one within another. Recall that considerable evidence has been found supporting the hypothesis that mitochondria and chloroplasts originated from prokaryotes that lived as endosymbionts inside other cells (see Chapter 21).

Horizontal gene transfer occurs between free-living organisms classified in different domains. In 2013, a team of researchers reported that horizontal gene transfers from free-living bacteria and archaea enabled the unicellular red alga *Galdieria sulphuraria* to adapt to harsh environments that are too hot, acidic, or toxic for most other eukaryotes. The study suggests that horizontal gene transfer continues to be a very important mechanism in evolution.

Based on what is now known about horizontal gene transfer, some systematists argue that the common ancestor of all living things may have been a *community* of species that traded their genes. Many systematists suggest that there is no simple tree of life and have proposed alternative hypotheses (FIG. 23-4). Based on analyses of hundreds of genes, some systematists hypothesize that horizontal gene transfer between bacteria and archaea gave rise to the eukaryotes. Horizontal gene transfer appears to be a continuous process among members of the three domains.

The evolution of systematics reflects the creative and dynamic process of science. Systematists are very responsive

Figure 23-4 Another way to represent the tree of life

The three-domain approach has been drawn to show horizontal gene transfer as a continuous process between domains and also among groups within each domain. Only some of the branches are labeled. The diagonal *brown arrow* represents mitochondrial endosymbiosis; the diagonal *green arrow* represents chloroplast endosymbiosis.

to new data; consequently, classification of organisms at all levels is a continuously changing process. Although many biologists are moving away from a hierarchical system, some suggest adding new groups so that the classical approach keeps up with new findings. Whatever approach is used, the goal of systematics is to base classification on evolutionary change and relationships.

CHECKPOINT 23.2

- What are the major groups of organisms that belong to each of the three domains? In which domain and kingdom would you classify each of the following: white willow, the bacterium *Escherichia coli*, tapeworm, and black bread mold?
- **CONNECT** In what specific ways does a cladogram give us information about the evolutionary relationships of groups of organisms?
- Contrast the two mechanisms—vertical and horizontal gene transfer—by which genes are transferred from one genome to another.

23.3 Reconstructing Evolutionary History

LEARNING OBJECTIVES

- 6 Critically review the difficulties encountered in choosing taxonomic criteria.

- 7 Apply the concept of shared derived characters to the classification of organisms.
- 8 Describe how analyses of molecular homologies contribute to the science of systematics.
- 9 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

A major goal of modern systematics is to reconstruct **phylogeny** (literally, “production of phyla”), the evolutionary history of any group of organisms from a common ancestor. In their efforts, systematists must employ a wide range of evidence, from shared traits (homologous traits) to geographic distributions to positions in strata (for fossils), and must incorporate our best understandings of evolutionary processes. As systematists determine evolutionary relationships among species and higher taxa, they build classifications based on the patterns of shared ancestry. Systematics is at the center of how we understand and explain the patterns of similarities and relationships of life-forms on Earth.

Once phylogenies are established, they help us answer other questions in biology. For example, phylogenies help us understand evolutionary patterns that might provide clues to the origin and spread of HIV and other pathogens (discussed later in this chapter). Phylogenies also help biologists identify new species and predict their characteristics, as well as understand biodiversity and ecological mechanisms. Systematists may classify a new species based on specific characters that it shares with other organisms in a particular taxon. They may then infer that the new species shares many other characters with organisms in that group.

As you read the following sections, remember that phylogenies are testable hypotheses. They are supported or falsified by the available data. Systematics proceeds by constantly re-evaluating data, hypotheses, and theoretical constructs. As new data are discovered and old data are reinterpreted, systematists modify their hypotheses. As a result, our understanding of how organisms are related and the way we classify organisms are continuously being revised. Systematics is a dynamic science that changes as biologists discover new species and use ever more sophisticated techniques to investigate the evolutionary relationships among organisms.

Recall that a **population** is made up of all the individuals of the same species that live in a particular area. A population has a dimension in space—its geographic range—and also a dimension in time. Each population extends backward in time. Somewhat like branches of a tree, a population may diverge from other populations enough to become a new species (which may be depicted by a new tree branch; see Chapters 19 and 20). Species have various degrees of evolutionary relationships with one another, depending on the degree of genetic divergence since their populations branched from a common ancestor.

Homologous structures are important in determining evolutionary relationships

The evidence suggests that some 380 to 400 million years ago a population of early fishlike vertebrates evolved. These animals, the early **tetrapods**, had four limbs instead of the pectoral and pelvic fins of their fish ancestors. Because all the modern amphibians, reptiles, birds, and mammals evolved from that group of early tetrapods, members of the modern taxa share

many traits. For example, the wings of bats, the front legs and paws of tigers, the front flippers of whales, and the front limbs of frogs all share similar bone structures because the genes for these bones were inherited from the same earliest tetrapods. We say that the bones are *homologous* among these animals (see Fig. 18-13). Based on their shared ancestry, the tetrapods are now classified in the group, **Tetrapoda**.

Although homologous similarities are very important to scientists for inferring phylogeny, similarities among species can occur for reasons other than homology. Similar structures sometimes evolve when unrelated or distantly related species become adapted to similar environmental conditions. Thus, wings may occur in two or more species not derived from a recent common ancestor. Recall from Chapter 18 that independent evolution of similar structures in distantly related organisms is known as **convergent evolution**. Sharks and dolphins have similar, but independently derived, body forms because they have become adapted to similar environments (aquatic) and lifestyles (predatory). Sometimes it is obvious that convergent evolution has occurred. In other cases, researchers must test their hypotheses using all available data.

Another challenge in deciding on homology is **reversal**, in which a trait reverts to its ancestral state. A reversal removes a similarity that had evolved. A characteristic that superficially appears homologous but is actually independently acquired by convergent evolution or reversal is described as exhibiting **homoplasy**. Distinguishing between homology and homoplasy can be challenging (FIG. 23-5).

Shared derived characters provide clues about phylogeny

Systematists rely on homologous traits for evidence of shared ancestry. However, they also distinguish among those homologous traits, determining which traits will help most for studying particular relationships. In making decisions about taxonomic relationships, the systematist first examines the

homologous characteristics in the largest group (such as phylum or class) of organisms being studied and interprets them as indicating the most *remote* common ancestry. These **shared ancestral characters** are features that were present in an ancestral species and remain present in all groups descended from that ancestor. For example, the vertebrae, present in all vertebrates (with the exception of the hagfishes), is an ancestral character for study of classes within the subphylum Vertebrata. Studying the presence or absence of the vertebrae does not help us discriminate among various classes of vertebrates (e.g., between amphibians and mammals) because all individuals in these classes (except the hagfishes) have vertebrae.

When two populations become separated and begin to evolve independently, some of their homologous traits change as a result of mutation, natural selection, and genetic drift. The novel traits that evolve and remain present in the descendant taxa are referred to as **shared derived characters**, or *synapomorphies*. Note that shared derived characters originate in a *recent* common ancestor and are present in its descendants. Species that share derived characters form a clade. Systematists use *shared derived characters* (recently evolved homologies) to identify points where groups diverged from one another. A trait viewed as a derived character in a more inclusive (broader) taxon may also be considered an *ancestral character* in a less inclusive (narrower) taxon. For example, vertebrae are a shared derived character among vertebrates, but an ancestral character among mammals.

More recent common ancestry is indicated by classification into less and less inclusive taxonomic groups with more and more specific shared derived characters. For example, the small bones in the middle ear are useful in identifying a branch point between reptiles and mammals. All tetrapods (amphibians, reptiles, birds, and mammals) have one bone, the stapes, present in the middle ear, but mammals have two additional bones, the incus and malleus, in the middle ear. The evolution of this derived character (three bones rather than one bone) was a unique event, and only mammals have these

GEORGE GRALL/National Geographic Creative

Edmund Brodie

Figure 23-5 Homology and homoplasy

These two salamander species (*Notophthalmus viridescens*, red eft stage, and *Plethodon cinereus*, red-backed salamander) share many skeletal features because they inherited these features from the same early salamander species that was their shared ancestor. This is an example of homology. However, the bright red color of the two species has independently evolved, which is an example of homoplasy.

bones. However, if we compare mammals with one another, the three ear bones are a shared ancestral character because all mammals have them. Consequently, they have no value for distinguishing among mammalian taxa. Other characters must be used to establish branch points among the mammals.

If we compare dogs, goats, and dolphins (which are all mammals), we find that dogs and goats have two nostrils at the tip of their snouts, whereas dolphins have their nostrils at the tops of their heads as a single or paired blowhole. Having nostrils at the tip of the snout is an ancestral trait in mammals and therefore cannot be used as evidence that dogs and goats share a more recent common ancestor. In contrast, the presence of a blowhole in dolphins is a derived character within mammals. When we compare dogs, dolphins, and whales, we find that dolphins and whales share this derived character, providing evidence that these animals evolved from a common ancestor not shared by dogs.

Systematists base taxonomic decisions on recent shared ancestry

Both dolphins and many fishes have streamlined body forms, but this similarity is homoplastic and does not indicate close evolutionary relationships. In contrast, dolphins share important homologous derived characters (synapomorphies) with mammals: mammary glands, which produce milk for the young; three small bones in the middle ear; and a muscular diaphragm that helps move air into and out of the lungs, to name just a few traits. Thus, our evidence suggests that dolphins and mammals share a common ancestor, and we classify dolphins as mammals.

Historically, people have thought of higher taxonomic groups as being comprised of species that share certain defining features. For example, previously someone might say that mammals are defined as vertebrates that possess hair. Modern systematics, with its emphasis on recognizing taxonomic groups based on shared genealogy (ancestry), requires a different perspective. Systematists do use traits like mammary glands, muscular diaphragm, and hair as evidence that dolphins should be classified as mammals. Dolphins are included within the Mammalia because all the available evidence suggests that they evolved from the same recent ancestor as the rest of the mammals. Even if dolphins evolved to completely lose all body hair, they would still be classified within the Mammalia because of their ancestry.

Another example was mentioned earlier in this chapter. The tetrapods are all those vertebrates that evolved from the first fish-like vertebrates that had limbs with joints and digits instead of fins. As the name suggests, tetrapods are the “four-legged” vertebrates. However, the taxonomic group Tetrapoda is not defined by the presence of four legs; in fact, many groups of animals that are classified as tetrapods have either no limbs (e.g., snakes and limbless lizards) or greatly modified limbs (e.g., whales and birds).

Molecular homologies help clarify phylogeny

When a new species evolves, it does not always exhibit obvious phenotypic differences when compared to closely related species. For example, two distinct species of fruit flies may

appear identical to us. Some of their DNA, proteins, and other molecules, however, are different. Such variations in the structure of specific macromolecules among species, just like differences in anatomical structure, result from mutations. Advances in molecular biology have provided the tools for biologists to compare the macromolecules of various organisms. In fact, organisms can now be identified by their molecular structure.

In 2003, scientists at the University of Guelph in Canada proposed in the British *Proceedings of the Royal Society* that we identify all living things by their unique sequences of nitrogenous bases in particular regions of DNA rather than by their physical structure. The DNA barcode initiative, directed by the Consortium for the Barcode of Life (CBOL), is based on the concept that scientists will find a particular region of DNA (1) that is present in all species, (2) that is relatively short and easy to sequence, and (3) for which each species has a unique sequence of nitrogenous bases. This DNA region would be a global tool for species identification. Currently, some scientists have agreed that the gene for the protein cytochrome oxidase subunit I may fit the requirements for eukaryotes, and they are attempting to determine the sequences for as many species as possible. The hope is that the relatively easy-to-determine DNA sequences will work like product barcodes, uniquely identifying each species at any stage of life, including eggs, seeds, or incomplete fragmented samples. More than 200 organizations worldwide are collaborators in CBOL's DNA barcode effort.

The science of **molecular systematics** focuses on molecular structure to clarify evolutionary relationships. DNA, RNA, and amino acid sequencing are used to compare the macromolecules of organisms being studied. Macromolecules that are functionally similar in two different types of organisms are considered homologous if their subunit sequence is similar. Such comparisons provide systematists with valuable information about the degree of relatedness among organisms. The more closely the subunit sequences of two species correspond, the more closely related the species are considered to be. The number of differences in certain DNA nucleotide sequences in two groups of organisms may approximately reflect how much time has passed since the groups branched from a common ancestor. (This can be true only when the mutations in DNA occur at a steady rate.) Thus, specific DNA sequences may be useful as **molecular clocks**.

Many systematists look to ribosomal RNA (rRNA) structure and the DNA sequences that code for the RNA in ribosomes (ribosomal DNA) to help determine phylogenies. All known organisms have ribosomes that function in protein synthesis, and the DNA nucleotide sequences coding for rRNA have been highly conserved during evolution. Recall that the division of organisms into three domains was based in large part on the comparison of rRNA by Carl Woese and his research team.

The ribosomes of archaea and bacteria contain three subunits of RNA, named in order of increasing size: 5S, 16S, and 23S. (These numbers are sedimentation coefficients, measures of relative size, used to characterize behavior of a particle when

centrifuged.) The DNA sequences for the 5S and 16S RNAs have been extensively used to determine evolutionary relationships among bacteria. These gene sequences for rRNA are useful because the number of base pairs is manageable, the DNA has shown little change over long evolutionary periods, and the genes show some species-specific variability among bacteria and archaea.

Researchers have also used comparison of the DNA sequences for rRNA to challenge the once widely accepted idea that fungi are closely related to plants. According to rRNA analysis, fungi are more closely related to animals than to plants. Animals and fungi share a more recent common ancestor, perhaps a flagellate, a one-celled protist that has one or more long, whiplike flagella (used for locomotion).

Because different genes can evolve at different rates, researchers now typically compare nitrogenous base sequences from many different genes of the organisms under study. Molecular sequence data have been sampled from the majority of all known species. The very precise tools provided by molecular biology have put systematics on the cutting edge of biological research.

Scientists at Broad's Genome Sequencing and Analysis program at the Massachusetts Institute of Technology (MIT) and at Harvard provided another example of applied molecular systematics (FIG. 23-6). They sequenced the genome of domestic dogs and compared 16 specific coding regions with the sequences found in 30 other living canids (members of the family Canidae to which the domestic dog belongs). The data they gathered enabled these investigators to construct a cladogram of the phylogenetic relationships of canids. They confirmed earlier research based on other DNA sequences as well as morphological traits showing that domestic dogs are most closely related to gray wolves.

Taxa are grouped based on their evolutionary relationships

Most known organisms were classified by biologists before the days of phylogenetics. Modern systematists use phylogenetic analysis to test these hypothesized relationships among groups of organisms. Based increasingly on molecular data, they either confirm or modify the work of earlier biologists. Using their data, systematists construct cladograms to reflect relationships among clades. Cladograms show that previous classifications reflect three different types of taxonomic relationships: monophyletic groups, paraphyletic groups, and polyphyletic groups.

A **monophyletic group** includes an ancestral species and all its descendants (FIG. 23-7a). It is defined by shared derived characters. Mammals, for example, have mammary glands that produce milk for the young, three small bones in the middle ear, and a muscular diaphragm. All mammals are thought to have evolved from a common ancestral mammal that had these shared derived characters, and all descendants of this ancestor are mammals. Monophyletic taxa are clades. They are referred to as “natural” groupings because they represent true evolutionary relationships and include all close relatives. **Sister taxa**,

How is the dog related to other canids?

HYPOTHESIS: Analysis of molecular data from a variety of canids will clarify the evolutionary relationships of canids.

EXPERIMENT: Researcher Kerstin Lindblad-Toh and her colleagues sequenced the genome of the domestic dog. They compared coding regions of more than 13,000 dog genes with corresponding human and mouse genes. Then they selected 12 exons and 4 introns and sequenced them in 30 of 34 living canids.

RESULTS AND CONCLUSION: Analysis of the comparisons of exon and intron nucleotide sequences allowed these researchers to build a cladogram of Canidae species. The data indicated that the dog is most closely related to the gray wolf. (Sequence divergences of nuclear exon and intron sequences are 0.04% and 0.21%, respectively.) The two African jackals (branch at left) are the sister group of this clade, suggesting an African origin for the canids.

SOURCE: Lindblad-Toh, K., et al., “Genome Sequence, Comparative Analysis and Haplotype Structure of the Domestic Dog,” *Nature*, Vol. 438 (Dec. 8, 2005).

Figure 23-6 Molecular phylogeny

Molecular similarities indicate that the domestic dog is closely related to the gray wolf. Note that some biologists list the scientific name for the domestic dog as *Canis familiaris*, but others, including the Smithsonian Institution and the American Society of Mammalogists, consider the dog a subspecies of the gray wolf (*Canis lupus*) and list its name as *Canis lupus familiaris*.

CONNECT According to the cladogram, which animal is most closely related to the wolf/domestic dog clade?

or sister groups, share a more recent common ancestor with one another than either taxon does with any other group shown on a cladogram. In Figure 23-7, taxon 2 and taxon 3 are sister taxa to each other; taxon 5 and taxon 6 are also sister taxa.

A **paraphyletic group** is a group that contains a common ancestor and some of, but not all, its descendants (FIG. 23-7b). Members of the group share ancestral characters. As discussed

Key Point

Groups of organisms can be described as **monophyletic**, **paraphyletic**, or **polyphyletic**. Only monophyletic groups are considered **clades**.

(a) Taxa 2 and 3 are a monophyletic group or **clade** (Group I). Taxa 1 through 6 also make up a monophyletic group (Group II). Each group includes a common ancestor and all its descendants.

(b) Taxa 4 and 5 make up a **paraphyletic group** (Group III). This group includes some of, but not all, the descendants of the recent common ancestor indicated at node D. Which taxon is not included?

(c) Group IV is **polyphyletic**. Members of this group (taxa 3 and 5) do not share the same recent common ancestor.

Figure 23-7 Evolutionary relationships

In all three figures, the branch point at node A represents the common ancestor of all taxa shown. Node B represents the common ancestor of taxa 2 through 6. Node C represents the common ancestor of taxa 2 and 3. Node D represents the common ancestor of taxa 4, 5, and 6. Node E represents the common ancestor of taxa 5 and 6. Common ancestry is the basis for making decisions about classification.

CONNECT Look at part (b). Consider the organisms that evolved from the ancestor at node D. Which of the taxa shown form a monophyletic group?

later in this chapter, the traditional class Reptilia is paraphyletic because it does not include all descendants of the most recent common ancestor of reptiles. Birds share a recent common ancestor with reptiles.

A **polyphyletic group** consists of several evolutionary lines that do not share the same recent common ancestor (FIG. 23-7c). Biologists might have mistakenly classified the members of such a group together because these organisms share similar (homoplastic) features arising from convergent evolution. Systematists try to avoid constructing polyphyletic taxa because they are unnatural and misrepresent evolutionary relationships. Polyphyletic taxa are sometimes accepted temporarily until research provides additional data.

CHECKPOINT 23.3

- How are shared ancestral characters and shared derived characters different? How is the concept of homology related to these concepts?
- Why don't shared ancestral characters provide evidence for relationships between organisms within a taxon that has those traits? Give an example.
- **CONNECT** How is molecular biology contributing to the science of systematics?
- Systematists prefer to recognize monophyletic taxa rather than polyphyletic taxa. Why?

23.4 Constructing Phylogenetic Trees

LEARNING OBJECTIVES

- 10 Contrast the traditional classification with the current classification of reptiles and birds.
- 11 Describe the construction of a cladogram by using outgroup analysis.
- 12 Apply the principle of parsimony to cladogram construction.

In the second half of the 20th century, several methodological and philosophical schools of systematics were in a sense competing for supremacy among biologists. Three major schools emerged—*phenetics* (also known as numerical taxonomy), *evolutionary taxonomy*, and **phylogenetic systematics**, also known as **cladistics**. Their approaches differed in terms of broad goals, the methodologies used, and the accepted naming systems. The debate among followers of these three approaches was at times quite forceful and animated. What has emerged is a loosely defined consensus that borrows modified techniques from all three approaches but largely adopts many of the concepts from phylogenetic systematics.

Biologists today generally agree that ideally the goal of systematics should be to reconstruct the genealogical (evolutionary) relationships among species and that the best evidence for such relationships can be found in the patterns of traits shared by organisms (homologous traits). For many traits, the differences between shared derived characters and shared ancestral characters can be distinguished, and these traits can be analyzed as outlined below following many approaches derived from phylogenetic systematics. Aspects of these approaches are described in the next few sections. In some cases, however, systematists cannot clearly separate ancestral and derived states for certain traits; there, the more statistical approaches derived from phenetics are employed to construct phylogenies.

One conflict from the 20th century that has persisted into the present concerns the naming of taxonomic groups. Most modern systematists agree that scientific names should reflect monophyletic groups because such names will generally carry the most meaning. For example, when someone uses a taxonomic name that reflects a monophyletic group, we immediately understand that the name reflects an ancestor and all its descendants. We understand that because of their relatedness, the species included in the monophyletic group are likely to share many homologous similarities. Although this approach seems almost intuitive, it is not without controversy, mostly because full adoption of this approach will require changes to traditional taxonomy.

As additional evidence is discovered, new monophyletic groups must be recognized. At the same time, systematists find that some traditional group names do not reflect monophyletic groups. These groups need to be discarded or redefined. For example, a new taxon is needed for Tetrapoda (discussed earlier in this chapter). The tetrapods include amphibians, reptiles (including birds), and mammals, and their ancestors can be traced back to the first vertebrate with four legs. All

available evidence suggests that the tetrapods are a monophyletic group and should be recognized as the group Tetrapoda.

More controversial is how traditional names that do not reflect monophyletic groups should be handled. Traditionally, the class Reptilia has been defined to include turtles, lizards, snakes, crocodilians, and dinosaurs. The phylogenetic evidence suggests that this group is paraphyletic because birds share a common ancestor with the saurischian dinosaurs yet are not included in the traditional Reptilia (**FIG. 23-8a**).

One solution would be to redefine the group Reptilia to include birds. Another solution is to abandon Reptilia as a taxon. Reptiles, birds, and mammals all have an **amnion**, a membrane that forms a fluid-filled sac around the embryo. Reptiles, birds, and a few mammals lay eggs. The fluid within the amnion prevents them from drying out. Thus, the amnion allows development in terrestrial environments. Animals with an amnion make up a monophyletic group, the **amniotes**, or Amniota (**FIG. 23-8b**).

Two large monophyletic groups within the Amniota are the **diapsids** (traditional reptiles and birds) and the mammals. Within the diapsid group, the **archosaurs** include the crocodiles, flying reptiles (the extinct pterosaurs), the extinct dinosaurs, and the birds. These groups are discussed in more detail in Chapter 32.

Outgroup analysis is used in constructing and interpreting cladograms

A crucial step in most cladistic analyses is **outgroup analysis**, a research method for estimating which attributes are shared derived characters in a given group of organisms (**FIG. 23-9**). An **outgroup** is a taxon that is considered to have branched off earlier than the taxa under investigation, the **ingroup**. An ideal outgroup is the closest relative of the group being studied, its sister taxon, and has not been highly modified since its origin. Recall that sister taxa evolved from the same recent common ancestor. Systematists argue that an outgroup is likely to retain the ancestral state for characters being used in the analysis, allowing the researchers to identify the evolutionary changes leading to derived characters. To help you understand outgroup analysis, we describe the specific example illustrated in Figure 23-9.

The first step in constructing a cladogram is to select the taxa, which may consist of individuals, species, genera, or other taxonomic levels. Here we use a representative group of eight chordates: the lancelet, lamprey, sunfish, frog, lizard, bear, chimpanzee, and human. (Chordates are animals that, at some time in their lives, have a cartilaginous, dorsal skeletal structure called a notochord; a dorsal, tubular nerve cord; and grooves in the wall of the pharynx.) The next step is to select the homologous characters to be analyzed. In our example we use seven characters. For each character, we must define all the different conditions, or states, as they exist in our taxa. For simplicity, we consider our characters to have only two different states: *present* or *absent*. Keep in mind that many characters used in cladistics have more than two states. For example, black, brown, yellow, and red may be only a few of the many possible states for the character of hair color.

The last, and often the most difficult, step in preparing the data is to organize the character states into their correct evolutionary order. For this step, we use outgroup analysis. In our example the

(a) The traditional approach to classification recognized the common ancestry of birds and reptiles, but assigned them to different classes. In this approach reptiles are a paraphyletic group.

Figure 23-8 Two approaches to the classification of reptiles and birds

Phylogenetic systematics, also known as cladistics, recognizes reptiles and birds as a monophyletic group.

lancelet, a small marine chordate with a fishlike appearance, is the chosen outgroup. It belongs to a taxon that is considered to have diverged earlier than any of the other taxa under investigation but to be closely related to vertebrates; thus, the lancelet represents an approximation of the ancestral condition for vertebrates. Therefore, the character state “absent” for a particular character state such as vertebrae is the ancestral condition, and the character state “present” is the derived condition for the characters in Figure 23-9.

A cladogram is constructed by considering shared derived characters

Our objective is to construct a cladogram that requires the fewest number of evolutionary changes in the characters. Taxa are grouped by the presence of shared derived characters. To form a valid monophyletic group, all members must share at least one derived character. Membership in a clade cannot be established by shared ancestral characters.

In our example notice that all taxa, except the outgroup lancelet, have vertebrae. We can therefore conclude that these seven vertebrate taxa form a valid clade. Next, among the seven vertebrate taxa, note that jaws are present in all groups except lampreys (a group of jawless vertebrates). Using these data, we construct a preliminary cladogram (see Fig. 23-9a).

Recall that the root, or base, of the cladogram represents the common ancestor for all taxa being analyzed. In

(b) Phylogenetic systematists (cladists) classify birds and reptiles together because they have a recent common ancestor and are a monophyletic group. The cladogram shows the branching points in the evolution of the major groups of reptiles. Lizards, snakes, and crocodiles are phenotypically similar, but crocodiles, dinosaurs, and birds are most closely related because they evolved most recently from a common ancestor (node C). Node E represents the branching of two clades of dinosaurs from a common ancestor and the subsequent branching of birds from the lineage of the saurischian dinosaurs.

Figure 23-9a, node A represents the common chordate ancestor from which the outgroup (lancelet) and the seven vertebrate taxa evolved. Similarly, node B represents the common ancestor of the vertebrates, and node C represents the common ancestor of the jawed vertebrates. Continuing with this procedure, note that among the six jawed taxa, all but sunfish have four limbs with digits (see Fig. 23-9b). Among the five groups with limbs, all but frogs have an amnion (see Fig. 23-9c). The branching process is continued, using the data in the table in the top center of the figure, until all clades are established (see Fig. 23-9d).

Each branch point represents a major evolutionary step

Notice that humans and chimpanzees share a recent common ancestor at node G in Figure 23-9d. This hypothesis is supported by the derived characters they share (synapomorphies).

WHY IS IT USED? Outgroup analysis is used to organize character states into their evolutionary order, that is, to reconstruct phylogeny.

HOW IS IT DONE?

- 1. Select the taxa of interest and the homologous characters to be analyzed.
- 2. Define the possible conditions, for example, present (P) or absent (A).
- 3. Here, the lancelet is selected as the outgroup; this taxon diverged earlier than any of the other taxa being considered. The lancelet represents an approximation of the ancestral condition.
- 4. Refer to the table at right as you follow steps (a) through (d) to build a cladogram.

KEY

A = Absent

P = Present

	CHARACTERS						
	Vertebrae	Jaws	Tetrapod (4 limbs)	Amnion	Mammary glands	Opposable thumb	Upright posture
TAXA							
Lancelet (outgroup)	A	A	A	A	A	A	A
Lamprey	P	A	A	A	A	A	A
Sunfish	P	P	A	A	A	A	A
Frog	P	P	P	A	A	A	A
Lizard	P	P	P	P	A	A	A
Bear	P	P	P	P	P	A	A
Chimpanzee	P	P	P	P	P	P	A
Human	P	P	P	P	P	P	P

Figure 23-9 Constructing a cladogram using outgroup analysis

In the same way, bears are more closely related to the human–chimpanzee clade than to any other clade considered in our example, as indicated by the common ancestor at node F.

Note that shared derived characters are nested. As you trace the tree from its root to its tips, each branch reflects the addition of one or more shared derived characters. When we compare the nodes, the order of divergence (branching) is

indicated by relative distance from the base of the diagram. The farther a node is located from the base of the cladogram, the more recently the group diverged. In our example node G represents the most recent divergence, and node A represents the most ancient divergence. Thus, in our example humans are closely related to chimpanzees (through node G) but more distantly related to bears (through node F). Therefore, biologists

(a) This cladogram, with its diagonal branches, illustrates the style most commonly used in this book.

(b) This cladogram is another way to depict the same relationships shown in (a).

assign humans and chimpanzees to a less inclusive taxon (order Primates), whereas humans, chimpanzees, and bears are assigned to a broader, more inclusive taxon (class Mammalia). In addition, the cladogram reveals that lizards are more closely related to the mammal clade than to frog, sunfish, or any other clade in our example. Can you explain why?

Two important concepts guide interpretation of cladograms. First, the relationships among taxa are determined only by tracing along the branches back to the most recent common ancestor and *not* by the relative placement of the branches along the horizontal axis. It is possible to represent the same relationships with many different types of branching diagrams (FIG. 23-10). Note that all three cladograms in this figure are equivalent. (Verify this fact by comparing the nodes and checking the relationships described earlier.) Thus, a tree can be rotated around its nodes. The branching relationships, not the order of the taxa or the size of the branches, are important.

A second important concept is that the cladogram tells us which taxa shared a common ancestor and how recently they shared a common ancestor. The ancestor itself remains unspecified. The cladogram does not establish direct ancestor–descendant relationships among taxa. In other words, a cladogram does not suggest that a taxon gave rise to any other taxon. Very specifically, the cladograms in Figures 23-9 and 23-10 do not suggest that the lampreys evolved before the other vertebrates or that the other vertebrates evolved from the lampreys, only that the lineage that eventually evolved into the lampreys separated from the rest of the vertebrates before the separation of the tetrapods from the fishes.

Note that any particular cladogram, such as those shown in Figures 23-8, 23-9, and 23-10, depicts only some of the nodes and branches in the tree of life. For example, in Figure 23-10a the single branch from node C that leads toward sunfish could

(c) This cladogram has rectangular branches and is rotated 90 degrees. However, it illustrates the same relationships as the cladograms in (a) and (b).

Figure 23-10 Cladogram styles

These three cladograms look very different, but they depict the same relationships. Remember that the relationships are depicted by which groups branch at the nodes. The length of the branches is not important.

be drawn to show thousands of nodes and tens of thousands of branches representing all the species of modern bony fishes. Cladograms used throughout this book will by necessity illustrate only particular nodes and branches of interest. The reader is always encouraged to think about which organisms have been left off any cladograms and where their favorite organisms might be placed. Where on Figure 23-10a should salamanders be placed?

WHY IS IT USED? Cladogram construction is used to choose between alternative hypotheses of evolutionary relationships by selecting the most accurate branching pattern.

HOW IS IT DONE? Systematists choose the simplest explanation to interpret the data.

1. Draw the possible cladograms.
2. Examine the relevant characters. In this example, character A = hair, B = mammary glands, and C = middle ear bones.
3. Note that in the first cladogram (hypothesis 1) all three characters examined had to evolve independently twice.
4. Hypothesis 2 is chosen because it requires that each character evolve only once.

Figure 23-11 Applying the principle of parsimony to cladogram construction

Systematists use the principles of parsimony and maximum likelihood to make decisions

When systematists consider the evolutionary relationships of organisms, they must choose between multiple, competing cladograms. How do they choose the most accurate branching pattern? The most common criterion is the principle of **parsimony**: they choose the simplest explanation to interpret the data. Parsimony, a guiding principle in many areas of research, is based on the experience that the simplest explanation is probably the correct one. Applied to choice of cladograms, parsimony requires that the cladogram with the fewest changes in characters (the one with the fewest homoplasies) be accepted as most probable (FIG. 23-11).

In actual practice it is often possible to generate several cladograms that are equally parsimonious. The cladograms that are selected are the ones with more shared derived characters. The cladograms with more homoplasies are excluded

because homoplasies are less likely to evolve than shared derived characters.

Systematists also use **maximum likelihood** to make decisions, especially when analyzing molecular data. Maximum likelihood is a statistical method that depends on probability (e.g., the probability that nucleotide sequences in DNA change at a constant rate over time). Complex computer programs analyze large data sets and report the probability of a particular tree.

CHECKPOINT 23.4

- **CONNECT** In what way do systematists use shared derived characters in their work?
- What is outgroup analysis?
- How do systematists apply the principle of parsimony?

23.5 Applying Phylogenetic Information

LEARNING OBJECTIVE

- 13** Describe how phylogenetic information can be applied to problems in other disciplines.

Modern systematics offers much more than simply a set of consistent species names and organized categories. The phylogenetic trees that are constructed contain useful information about the relationships among the organisms involved. This information can be applied to problems in many disciplines, including in ecology, evolution, and medicine.

When combined with other data, phylogenetic trees can be used to investigate the evolutionary histories of entire groups of organisms as well as the evolutionary changes that have occurred in specific traits. For example, phylogenetic trees based on the DNA sequences of modern humans combined with information on the geographic homelands of those humans are helping us understand the pathways used by humans as they originally dispersed out of Africa to inhabit the rest of the world (see Chapter 22).

Phylogenetic information has proven important in medical research and often has public health implications. **Human immunodeficiency virus (HIV)**, the virus that causes **acquired immunodeficiency syndrome (AIDS)** in humans, has had a devastating effect on humans since it first became prevalent in the 1980s. A major medical question concerned the origin of this virus. HIV is a **lentivirus**, a group of retroviruses (viruses that use RNA as their genetic material). Scientists have been able to determine the sequences of nucleotides in the RNA of many strains of HIV that have infected humans around the world. Researchers have sequenced somewhat similar viruses, called SIV viruses, that infect other primate species. Systematists have used these nucleotide sequences to generate phylogenetic trees for the viruses (FIG. 23-12).

When researchers mapped the primate host species onto the phylogeny for the viruses, they found that HIV-2, the somewhat less virulent virus, is most closely related to an SIV virus in a species of monkey (sooty mangabey). The more virulent HIV-1 strains have evolved from a virus that infected chimpanzees. The phylogenetic data were critically important in showing that precursors to HIV probably jumped from other primates to humans several times before the onset of the HIV epidemic. (HIV is discussed further in Chapter 45.)

This type of phylogenetic research has important public health implications. Many primate species are hosts for human pathogens that have spread into human populations, causing epidemics. Understanding the source and spread of

Figure 23-12 Understanding the origins of HIV infection in humans

The human immunodeficiency viruses (HIVs) and the related simian immunodeficiency viruses (SIVs) are lentiviruses. A phylogenetic analysis of nucleotide sequences for this group of viruses gives insight into the origins of HIV infection in humans. There are two major types of HIV, HIV-1 and HIV-2, with multiple strains within each of these types. Groups M, N, and O of HIV-1 are shown in the cladogram. HIV-1, group M, has affected millions of people around the world. Although all the HIV types and strains are from humans, different strains of SIV have been isolated from other species of primates. The cladogram shows four different strains of SIV isolated from chimpanzees, two SIV strains isolated from sooty mangabey monkeys, and three SIV strains isolated from other species of monkeys. The branching pattern derived from this phylogenetic analysis shows that the different strains of HIV-1 and HIV-2 have evolved separately from the various strains of SIV. Chimpanzees were the original source of the HIV-1 viral strains and sooty mangabey monkeys were the original source of the HIV-2 viral strains.

these infections may lead to prevention measures that mitigate or prevent future epidemics.

Many evolutionary questions remain. New hypotheses about how organisms are related suggest new taxonomic schemes. Systematics offers tools to help us test these hypotheses. In Chapters 24 through 32, we explore many evolutionary puzzles and discuss current hypotheses about relationships and classifications of organisms.

CHECKPOINT 23.5

- **CONNECT** How does modern systematics help medical researchers?

Summary: Focus on Learning Objectives

23.1 Classifying Organisms (page 479)

- 1 State two justifications for the use of scientific names and classifications of organisms.
 - **Systematics** is the scientific study of the diversity of organisms and their evolutionary relationships. **Taxonomy** is the branch of systematics devoted to naming, describing, and classifying organisms. **Classification** is the process of arranging organisms into groups based on similarities that reflect evolutionary relationships.
 - Scientific names allow biologists from different countries with different languages to communicate about organisms. Biologists in distant locations must know with certainty that they are studying the same (or different) organisms.
 - Classifications help biologists organize their knowledge.
- 2 Describe the binomial system of naming organisms and arrange the Linnaean categories in hierarchical fashion from most inclusive to least inclusive.
 - In the **binomial system of nomenclature**, the basic unit of classification is the species.
 - The name of each species has two parts: the **genus** name followed by the **specific epithet**. Both names are italicized.
 - The hierarchical system of classification includes **domain, kingdom, phylum, class, order, family, genus, and species**. Each formal grouping at any given level is a **taxon**.

23.2 Determining the Major Branches in the Tree of Life (page 480)

- 3 Describe the three domains and argue for and against classifying organisms in these domains. (Compare this approach with using kingdoms as the main rank of classification.)
 - The three-domain classification system assigns organisms to domains **Archaea, Bacteria, or Eukarya**. The domain classification is based on molecular data.
 - Domain Eukarya includes the fungi, plants, animals, and protists.
 - Some systematists recognize the kingdoms **Archaea, Bacteria, Fungi, Plantae, and Animalia**. Several “super-groups” composed of mainly unicellular, mainly aquatic eukaryotic organisms were formerly classified as kingdom Protista. Members of Archaea and Bacteria are prokaryotes. The fungi, which include molds, yeasts, and mushrooms, absorb nutrients produced by other organisms. Kingdoms Plantae and Animalia both consist of multicellular eukaryotes. For additional characteristics of the kingdoms, refer to Table 23-2. As new data are interpreted, organisms assigned to these kingdoms often must be reclassified.
- 4 Interpret a cladogram, describing the meaning of its specific nodes and branches.
 - In a **cladogram**, each *branch* represents a **clade**, a group of organisms with a common ancestor. Each *node*, or branching point, represents the splitting of two or more new groups from a common ancestor. The node represents the *most recent common ancestor* of the clade represented by the branches. The *root* represents the most recent common ancestor of all the clades shown in the tree.

- We can determine the relationships among taxa by tracing along the branches back to the nodes. The cladogram indicates which taxa shared a recent common ancestor and how recently they shared that ancestor compared to other groups.
- 5 Differentiate between vertical and horizontal gene transfer and explain their importance in understanding systematics.
 - In **vertical gene transfer**, genes are transmitted from parent to offspring within the same species.
 - In **horizontal gene transfer**, genes are exchanged between one genome and another within one taxon or between genomes in different taxons. Genes move from one individual to another or from one species to another species in the same generation.

23.3 Reconstructing Evolutionary History (page 485)

- 6 Critically review the difficulties encountered in choosing taxonomic criteria.
 - Systematists seek to determine evolutionary relationships, or **phylogeny**, based on shared characteristics. **Homology**, the presence in two or more species of a trait derived from a common ancestor, implies evolution from a common ancestor.
 - Some seemingly homologous characters are acquired independently by **convergent evolution**, independent evolution of similar structures in distantly related organisms, or by **reversal**, reversion of a trait to its ancestral state. The term **homoplasy** refers to superficially similar characters that are not homologous.
- 7 Apply the concept of shared derived characters to the classification of organisms.
 - **Shared ancestral characters** suggest a distant common ancestor.
 - **Shared derived characters** (synapomorphies) indicate a more recent common ancestor and can be used as evidence for constructing cladograms.
- 8 Describe how analyses of molecular homologies contribute to the science of systematics.
 - **Molecular systematics** depends on molecular structure to clarify phylogeny. Comparisons of nucleotide sequences in DNA and RNA, and of amino acid sequences in

proteins, provide important information about how closely organisms are related.

9 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

- A **monophyletic group**, or **clade**, includes all the descendants of the most recent common ancestor.
- A **paraphyletic group** consists of a common ancestor and some of, but not all, its descendants.
- A **polyphyletic group** consists of organisms that evolved from different recent ancestors.

23.4 Constructing Phylogenetic Trees (page 490)

10 Contrast the traditional classification with the current classification of reptiles and birds.

- Modern systematists agree that taxa must be monophyletic. Each monophyletic group consists of a common ancestor and all its descendants. Phylogenetic systematists (cladists) use shared derived characters to determine relationships among groups of organisms.
- Contemporary systematists classify reptiles and birds in a single clade.

11 Describe the construction of a cladogram by using outgroup analysis.

- Cladists use shared derived characters to reconstruct evolutionary relationships and diagram these relationships in cladograms. They use **outgroup analysis** to determine which characters in a given group of taxa are ancestral and which are derived.
- An **outgroup** is a taxon that diverged earlier than any of the other taxa being investigated.

12 Apply the principle of parsimony to cladogram construction.

- **Systematists** choose the simplest explanation to interpret the data—the principle of **parsimony**.

23.5 Applying Phylogenetic Information (page 495)

13 Describe how phylogenetic information can be applied to problems in other disciplines.

- Understanding how species are related can help scientists answer questions and solve problems in other disciplines. For example, phylogenetic information has helped us better understand the origin and transmission of HIV.

Test Your Understanding

Know and Comprehend

1. The mold that produces penicillin is *Penicillium notatum*. *Penicillium* is the name of its (a) genus (b) order (c) family (d) species (e) specific epithet
2. Decomposers such as molds and mushrooms belong to which domain and kingdom? (a) Eukarya, Plantae (b) Bacteria, Archaea (c) Archaea, Fungi (d) Eukarya, Archaea (e) Eukarya, Fungi
3. Each branching point in a cladogram (a) is called a root (b) represents a clade (c) represents the divergence of two or more groups from a common ancestor (d) represents horizontal gene transfer (e) marks the divergence of two kingdoms
4. The presence of homologous structures in two different groups of organisms suggests that (a) the organisms evolved from a common ancestor (b) convergent evolution has occurred (c) they belong to a polyphyletic group (d) homoplasy has occurred (e) independently acquired characters may evolve when organisms inhabit similar environments
5. Dolphins and humans both have the ability to nurse their young, whereas the less closely related sharks do not. The ability to nurse their young is (a) a shared derived character of fish and mammals (b) a shared ancestral character of all vertebrates (c) a shared derived character of mammals (d) an example of homoplastic behavior (e) an example of reversal
6. A group of organisms that includes a recent common ancestor and all its descendants is (a) polyphyletic (b) paraphyletic (c) monophyletic (d) an example of horizontal gene transfer (e) a sister group

7. In cladistic analysis, (a) ancestral characters are used to reconstruct phylogenies (b) characters must be homoplastic (c) polyphyletic groups are preferred (d) outgroup analysis is rarely used (e) shared derived characters are the preferred evidence for relatedness
8. When systematists apply the principle of parsimony, they (a) choose the cladogram that requires the fewest changes in characters as the most probable explanation to interpret the data (b) select multiple hypotheses to explain each relationship (c) do not use outgroups (d) typically use a polyphyletic approach (e) hypothesize that the most complex explanation is most probably the correct one

Apply and Analyze

9. In interpreting a cladogram, (a) we can identify the specific ancestor of each taxon by tracing each branch back to the node closest to the root (b) taxa on the right side of a cladogram have evolved from the taxa on the left side (c) the relative placement of smaller branches allows us to determine the number of years since a particular taxon has evolved (d) we can determine relationships by tracing along the branches back to the most recent common ancestor (e) we must first identify horizontal gene transfer
10. What are some of the criteria and tools biologists might use to assign the different types of protists to monophyletic groups?
11. What are the advantages of using domains, rather than kingdoms, as the highest rank of classification?

Evaluate and Synthesize

12. **EVOLUTION LINK** Are members of a clade similar because they share a common ancestor, or do they belong to the same clade because they are similar?
13. **EVOLUTION LINK** The TATA-binding protein (TBP) is thought to be necessary for transcription in all eukaryotic cell nuclei. Studies show that archaea, but not bacteria, have a protein structurally and functionally similar to TBP. What does this similarity suggest regarding the evolution of archaea, bacteria, and eukaryotes? How might knowledge of this similarity affect how systematists classify these organisms?
14. **VISUALIZE** Construct a cladogram based on the following data. Mosses are plants with no vascular tissue. Horse-tails, ferns, gymnosperms (pines and other plants with naked seeds), and angiosperms (flowering plants) are all vascular plants. Seeds are absent in all but the gymnosperms and angiosperms. Angiosperms are the only seed plants with flowers. (*Hint:* To help you construct the cladogram, draw a simple table showing which characters are present in each group. See Fig. 23-9.)

15. **INTERPRET DATA** What kind of grouping is represented by the bracketed area in the illustration? What type of group is formed by taxon 2 and taxon 3? What type of group is formed by taxa 2, 4, and 6?

24

Viruses and Subviral Agents

During the late 1800s, botanists searched for the cause of tobacco mosaic disease, which stunts the growth of tobacco plants and gives the infected tobacco leaves a spotted, mosaic appearance. The investigators found that they could transmit this disease to healthy plants by daubing their leaves with the sap of diseased plants. In 1892, Dmitri Ivanowsky, a Russian botanist, showed that the sap was still infective after it had been passed through porcelain filters designed to filter out all known bacteria. A few years later, in 1898, Martinus Beijerinck, a Dutch microbiologist, provided evidence that the agent that caused tobacco mosaic disease had many characteristics of a living organism. However, it appeared that the infective agent could reproduce only within a living cell. Beijerinck named the infective agent *virus* (from the Latin word “virus,” which means “poison”). Tobacco mosaic virus was the first virus to be recognized.

Early in the 20th century, scientists discovered other infective agents, like those responsible for tobacco mosaic disease, that could cause disease in animals or kill bacteria. These pathogens were so small that they could not be seen with the light microscope. They also passed through filters that removed bacteria. Curiously, they could not be grown in laboratory cultures unless living cells were present. The development of the electron microscope in the 1930s made it possible to see viruses for the first time.

Most of the viruses that infect animals, plants, and bacteria were identified during the second half of the 20th century.

KEY CONCEPTS

- 24.1** A virus is a small particle consisting of a nucleic acid core surrounded by a protein coat; a virus must infect a living cell in order to reproduce.
- 24.2** Viruses can be classified based on their host range, what type of nucleic acid they have, and whether the nucleic acid is single-stranded or double-stranded.
- 24.3** In a lytic reproductive cycle, a virus uses the host cell's molecular machinery to replicate itself, destroying the host cell in the process. In a lysogenic cycle, the viral genome becomes integrated into the host DNA and is then called a “provirus.”
- 24.4** Viruses infect the cells of organisms in each domain; most viruses are not harmful and many are beneficial to their host. However, some viruses cause serious diseases in plants and animals.
- 24.5** Three different hypotheses suggest how viruses may have originated and evolved.
- 24.6** Subviral agents, which include satellites, viroids, prions, and defective interfering particles (DIPs), are smaller and simpler than viruses.

PHOTO: An emerging virus. TEM (color-enhanced) of Ebola viruses (light blue). Ebola virus causes Ebola virus disease. Scott Camazine/Alamy Stock Photo

Viruses cause many plant diseases and are responsible for billions of dollars in crop losses each year. You may recognize some of the many human viral diseases, such as rabies, influenza, and herpes. You have probably received vaccinations for many childhood viral diseases, including polio, rubella (German measles), mumps, and chickenpox. *Emerging viruses* are new viruses that appear suddenly or move into new areas. They may cause epidemics or even pandemics (global epidemics). HIV (human immunodeficiency virus), which causes AIDS, is an important example. More recent emerging viruses include Zika virus and Ebola virus (see photograph).

Viruses make up a large component of Earth's biomass. Their huge numbers make up for their small size and weight. Viruses influence many ecological processes. For example, they kill large amounts of marine biomass each day, contributing significantly to the recycling of carbon and nutrients. Viruses adapt to their environments through evolution. They also influence the biodiversity of other organisms by transferring their own genes into the genetic material of their hosts. Viruses can also transfer eukaryotic genes from one organism to another, crossing species boundaries. The discovery of giant viruses has raised new questions about the structure, genomes, origin, and phylogenetic relationships of viruses.

In this chapter we examine the characteristics and diversity of viruses as well as the smaller subviral agents, viroids, prions, and defective interfering particles. Although biologists do not consider viruses to be living things, we include them in the diversity unit of *Biology* because they have some characteristics of life and because they impact all living organisms.

24.1 The Status and Structure of Viruses

LEARNING OBJECTIVES

- 1 Contrast a virus with a cellular organism.
- 2 Describe the structure of a virus.

A **virus** is a very small infective agent that consists of a core of nucleic acid and is dependent on a living host. The study of viruses is called *virology*, and biologists who study viruses are *virologists*. Most biologists view viruses as non-living particles because they are not composed of cells and they cannot carry on metabolic activities or reproduce on their own. They do not have the components necessary to carry on cellular respiration or to synthesize proteins and other molecules.

Viruses do contain the nucleic acids necessary to make copies of themselves. They replicate by invading living cells and commandeering their metabolic machinery. To multiply, a virus must *infect* a cell in which it can replicate. Thus, viruses are *obligate intracellular parasites*; they survive only by using the resources of a *host cell*, the cell the virus invades. Viruses infect all types of organisms, including bacteria, archaea,

protists, plants, fungi, and animals. Some viruses even infect other viruses. Interestingly, viruses evolve by natural selection. For these reasons, most biologists view viruses as being at the edge of life, although a few argue that they are very simple life-forms.

Viruses are very small

Most known viruses are very small, ranging in size from 20 to 300 nm. (Recall that a nanometer is one-thousandth of a micrometer.) The poliovirus is about 30 nm in diameter (about the size of a ribosome). If we could line these viruses up end to end, it would take about 100 of them to reach the length of an average bacterium! A poxvirus that causes smallpox can measure up to 300 nm long and 200 nm wide.

The paradigm that all viruses are very small and simple, with very small genomes, has been challenged by the discovery of giant viruses. The genus *Mimivirus* was discovered in 2004, followed by *Megavirus* in 2011 and *Pandoravirus* in 2013. *Pandoravirus salinus* approaches 1 μm in length and is about 0.5 μm wide, larger than many bacteria and some eukaryotic cells. Only 7% of the genes from *Pandoravirus salinus* match with existing gene databases. *Pandoravirus* was first discovered by French researchers in sediment off the coast of Chile and, like the other giant viruses, it infects amoebas.

A virus consists of nucleic acid surrounded by a protein coat

The nucleic acid core of the virus is surrounded by a protein coat called a **capsid**. Microbiologists use the term *virion* to refer to the complete virus particle that is outside a host cell in a dormant state. The virion is the form in which the virus moves from the cell in which it was produced to a new host cell in which it can replicate its genome. However, here we will use the term *virus* in a broad sense, even when referring to virions.

A typical virus contains *either* deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), not both. In 2012, however, researchers discovered an RNA–DNA hybrid virus in a high temperature acidic California lake. Further studies have found a few other similar RNA–DNA hybrids in marine environments.

The nucleic acid of a virus can be single-stranded or double-stranded. Thus, a virus can have single-stranded (ss) DNA, double-stranded (ds) DNA, ssRNA, or dsRNA. As we will discuss, the type of nucleic acid is important in classifying viruses. The virus genome typically consists of 5000 to more than 100,000 bases or base pairs (depending on whether it is single-stranded or double-stranded). Again, the giant viruses are exceptions. *Megavirus* has seven transfer RNAs and some metabolic genes never before identified in any other virus. Researchers have sequenced the double-stranded DNA genomes of two species of *Pandoravirus* and reported that they range from 1.9 to 2.5 million base pairs. The species with

(a) TEM of tobacco mosaic virus. This rod-shaped virus has a helical arrangement of capsid proteins.

(c) Color-enhanced TEM of HIV, the virus that causes AIDS. The virus is leaving a host cell (pink). The virus is enclosed in an envelope (green) derived from the host's plasma membrane. Viral proteins project from the envelope. The capsid of the virus is shown in yellow.

(b) Color-enhanced TEM of an adenovirus. The capsid is composed of 252 subunits (visible as tiny ovals) arranged into a 20-sided polyhedron. Twelve of the subunits have projecting glycoprotein spikes that permit the virus to recognize host cells.

(d) Color-enhanced TEM of T4 bacteriophage. This virus has a polyhedral head and a helical tail. The virus attaches to the cell wall of the bacterial host by its tail fibers.

Figure 24-1 The structure of a virus

A virus consists of a DNA or RNA core surrounded by a protein coat called a capsid. The capsid is made up of protein subunits called capsomers. Some viruses have an outer membranous envelope surrounding the capsid.

the largest genome has 2556 proposed protein-coding genes (only 6% of which match known proteins).

The capsid is a protective protein coat

The capsid consists of protein subunits called *capsomers*. The capsomers determine the shape of the virus. Capsids generally are helical, polyhedral, or a combination of both shapes. Helical viruses, such as the tobacco mosaic virus (TMV), appear as long rods or threads (FIG. 24-1a). Its capsid is a hollow cylinder made up of proteins that form a groove into which the RNA fits.

Polyhedral viruses, such as the adenoviruses (which cause a number of human illnesses, including some respiratory

infections), appear somewhat spherical (FIG. 24-1b). Its capsomers are organized in equilateral triangles. The capsid of a large virus can consist of several hundred capsomers. The most common polyhedral structure is an *icosahedron*, a structure with 20 identical surface faces (each face is a triangle). The human immunodeficiency virus (HIV) that causes AIDS is an enveloped virus (see next section) (FIG. 24-1c).

Some viruses have both helical and polyhedral components. Viruses that infect bacteria are called *bacteriophages*, or simply *phages* (FIG. 24-1d). The T4 phage that infects the bacterium *Escherichia coli* consists of a polyhedral “head” attached to a helical “tail.” Many phages have this shape. Many phages also have tail fibers that attach to the host cell.

Figure 24-2 Comparison of naked and enveloped viruses

As the virus leaves the host cell, the host's plasma membrane wraps around the virus, forming the envelope. The envelope contains proteins encoded by the virus.

Some viruses are surrounded by an envelope

Some viruses, called *enveloped viruses*, have an outer membranous envelope that surrounds the capsid. Typically, the virus acquires the envelope from the host cell's plasma membrane as it leaves the host cell (FIG. 24-2). Interestingly, while inside the host cell, the virus directs the synthesis of certain proteins, which are then inserted into the host's plasma membrane. Thus, the viral envelope consists of phospholipids and proteins of the host's plasma membrane as well as distinctive proteins encoded by the virus itself. Some viruses possess envelope glycoproteins that extend out from the envelope as spikes. As we will discuss, these glycoprotein spikes can be very important in the virus's interaction with the host cell.

CHECKPOINT 24.1

- **CONNECT** What characteristics of a living organism are absent in a virus?
- What are the structural components of a virus?

24.2 Classification of Viruses

LEARNING OBJECTIVE

3 Identify three characteristics used to classify viruses.

502 / Chapter 24

Viruses present a taxonomic challenge to biologists because they do not have the characteristics that define living organisms (see Chapter 1). They are not cellular, they do not carry on metabolic activities, and they reproduce only by taking over the reproductive machinery of other cells. Viruses do not manufacture proteins and so do not have distinctive rRNA. For these reasons, viruses are not classified in any of the three domains.

Viruses can be classified based on their **host range**, the types of host species a specific virus (or other type of infectious agent) can infect. They may be referred to as plant viruses, animal viruses, bacterial viruses, and so on. Viruses are more formally classified into taxa from species to orders. The International Committee on Taxonomy of Viruses (ICTV), a group of virologists, decides on specific criteria for classifying and naming viruses. Recently, based on host range and other characteristics, the ICTV classified viruses into 7 orders, 111 families, 488 genera, and nearly 3000 species. Virus family names include the suffix *-viridae*. Note that this classification system is not a traditional Linnaean system; it does not assign viruses to domains, kingdoms, or phyla.

The Baltimore classification system classifies viruses based on the type of nucleic acid the virus contains, whether the nucleic acid is single-stranded or double-stranded, and how mRNA is produced. Other traits considered in viral classification are the size and shape of the virus, the presence of an envelope, and the method by which the virus is transmitted from host to host.

CHECKPOINT 24.2

- What criteria would you use to classify a virus?

24.3 Viral Replication

LEARNING OBJECTIVES

- 4 Characterize bacteriophages.
- 5 Contrast a lytic cycle with a lysogenic cycle.

As we have discussed, viruses reproduce, but only within the complex environment of the living host cells they infect. Viruses use their genetic information to force their host cells to replicate their viral nucleic acid and make the proteins they need. They take over the transcriptional and translational mechanisms of the host cell.

Bacteriophages infect bacteria

Much of our knowledge of viruses has come from studying **bacteriophages** (“bacteria eaters”), more simply referred to as **phages**. These viruses can be cultured easily within living bacteria in the laboratory. Microbiologists have identified more than 5000 phages. Bacteriophages are among the most complex viruses (see Fig. 24-1d). Their most common structure consists of a long nucleic acid molecule (usually dsDNA) coiled within a polyhedral head. Most have a tail, which may be contractile and may function in penetration of the host cell.

Archaeal viruses, first described in 1974, attack archaea in a manner similar to bacteriophages. Over 50 archaeal viruses have been identified, with most having dsDNA and a head and tail structure similar to bacteriophages. Some archaeal viruses, however, have unique forms different from any other viruses (making them more morphologically diverse than bacteriophages). As more archaeal viruses are identified and studied, we will better understand evolutionary relationships between viruses and their hosts across domains.

Phages have been clinically used to treat infection for close to a century. Although abandoned in Western countries after the discovery of sulfa drugs and antibiotics in the 1940s, they have continued to be commonly used in member countries of the former Soviet Union to treat patients. Antibiotics, which have long been more dependable and easier to use, are increasingly less effective than in the past due to the widespread and escalating problem of bacterial resistance. Phage therapy, alone and paired with antibiotics, is again a focus of research in the United States as well as in Europe.

Phages are being engineered to specifically destroy particular bacteria due to their ability to target specific host species. Scientists are also genetically engineering phages so that bacteria will be slower to evolve resistance to them. A fast-acting blood culture test uses bacteriophages to identify and determine if *Staphylococcus aureus* bacteria are present and if they have resistance to methicillin. This new test yields results from in vitro testing in 5 hours compared to standard testing methods, which require 2 to 3 days.

Phage therapy also has applications in dentistry, veterinary medicine, agriculture, and food science. For example, certain phages can kill deadly strains of *E. coli* in cattle. These bacteria do not appear to make cattle ill but can cause illness

and death in people who eat contaminated, undercooked ground beef.

Bacteriophages are now commonly used to identify and eradicate target bacteria present in food products and food preparation facilities. Sprays containing bacteriophages are being used to destroy surface bacteria in clinical settings and to prevent bacterial growth on medical instruments, catheters, and surgical materials.

Viruses replicate inside host cells

Viruses infect bacterial, archaeal, plant, and animal cells in basically similar ways. We will focus on phage infection of bacteria because this process is best understood. The reproductive cycle of viruses begins with a virus coming into contact with a host cell. The virus typically attaches to the surface of the host cell. The viral nucleic acid must enter the host cell and synthesize the components it needs to reproduce itself. Then viral components are assembled, and viruses are released from the cell, ready to invade other cells. Two types of viral reproductive cycles are lytic and lysogenic cycles.

Lytic reproductive cycles destroy host cells In a **lytic cycle**, the virus lyses (destroys) the host cell. When the virus infects a susceptible host cell, it forces the host to use its metabolic machinery to replicate viral particles. Viruses that have only a lytic cycle are described as *virulent*, which means that they cause disease and often death.

Five steps are typical in lytic viral reproduction (FIG. 24-3):

1. **Attachment (or adsorption).** The virus attaches to specific receptors on the host cell. This process ensures that the virus infects only its specific host.
2. **Penetration.** The virus penetrates the host plasma membrane and moves into the cytoplasm. Many viruses that infect animal cells enter the host cell intact. Some phages inject only their nucleic acid into the cytoplasm of the host cell; the capsid remains on the outside.
3. **Replication and synthesis.** The viral genome contains all the information necessary to produce new viruses. Once inside a host cell, the virus degrades the host-cell nucleic acid. The virus then uses the molecular machinery of the host cell to replicate its own nucleic acid and produce viral proteins. Many antiviral drugs interfere with replication of viral nucleic acid.
4. **Assembly.** The newly synthesized viral components are assembled into new viruses.
5. **Release.** Assembled viruses are released from the cell. Generally, lytic enzymes, produced by the phage late in the replication process, destroy the host plasma membrane. Phage release typically occurs all at once and results in rapid cell lysis. In contrast, animal viruses are often released slowly or bud off from the plasma membrane.

Once released, the viruses infect other cells, and the process begins anew. The time required for viral reproduction, from attachment to the release of new viruses, varies from less than 20 minutes to more than 1 hour.

Key Point

Viruses reproduce by seizing control of the metabolic machinery of a host cell. In a lytic infection, the viruses destroy the host cell.

(a) The sequence of events in a lytic infection.

(b) Color-enhanced TEM of phages infecting a bacterium, *Escherichia coli*.

Figure 24-3 The sequence of events in a lytic infection. Virulent bacteriophages kill their host cell during each cycle of infection.

PREDICT Would the phage components be able to infect other bacteria if they were released prior to assembly?

How do bacteria protect themselves from phage infection? You may recall from Chapter 15 that bacteria produce *restriction enzymes*, enzymes that cut up the foreign DNA of the phage. This action prevents the phage DNA from duplicating. The bacterial cell protects its own DNA by slightly modifying it after replication so that the restriction enzyme does not recognize the sites it would cut.

In lysogenic cycles, temperate viruses integrate into the host DNA Temperate phages do not immediately destroy their hosts. These phages alternate between a lytic cycle and a lysogenic cycle. In a **lysogenic cycle**, the viral genome becomes integrated into the host bacterial DNA. The integrated virus is called a **prophage**, or **provirus**. When the bacterial DNA replicates, the prophage also replicates (FIG. 24-4). In this way, the prophage is passed on to new generations of the original infected cell. The viral genes that code for viral structural proteins may be repressed indefinitely. The temperate phage lambda (designated by the Greek letter λ) is a model organism used to study temperate viruses.

Certain external conditions (such as ultraviolet light and X-rays) cause temperate viruses to revert to a lytic cycle and then destroy their host. Sometimes temperate viruses become lytic spontaneously.

Bacterial cells carrying prophages are called *lysogenic cells*. Such bacterial cells may exhibit new properties. This type of change is called **lysogenic conversion**. An interesting example involves the bacterium *Corynebacterium diphtheriae*, which causes diphtheria. Two strains of this species exist, one that produces a toxin (and causes diphtheria) and one that does not. The only difference between these two strains is that the toxin-producing bacteria are infected by a specific temperate phage. The phage DNA codes for the powerful toxin that causes the symptoms of diphtheria. Similarly, the bacterium *Clostridium botulinum*, which causes botulism, a serious form of food poisoning, is harmless unless it contains certain prophage DNA that induces synthesis of the toxin.

CHECKPOINT 24.3

- VISUALIZE** What are the steps in a lytic cycle? Draw diagrams to illustrate your answer.
- How is a lysogenic cycle different from a lytic cycle?

24.4 Viral Diseases

LEARNING OBJECTIVES

- Contrast viral infection of plants and animals, and identify specific diseases caused by viruses.
- Describe the reproductive cycle of a retrovirus, such as human immunodeficiency virus (HIV).

Key Point

In a lysogenic cycle, temperate phages integrate their nucleic acid into the host genome. The prophage replicates when the bacterial DNA replicates.

Figure 24-4 The sequence of events in a lysogenic cycle. Temperate phages integrate their nucleic acid into the DNA of their bacterial host. The integrated viral DNA is called a prophage. The bacterium is called a lysogenic cell.

PREDICT How do temperate phages benefit from integrating into the bacterial DNA?

Sir Peter Medawar, a winner of the 1960 Nobel Prize in Physiology or Medicine, defined a *virus* as “a piece of bad news wrapped in protein.” Viruses that are **pathogens** are responsible for some very serious diseases, including Ebola hemorrhagic fever, rabies, influenza (flu), hepatitis, and AIDS. However, although viruses must infect cells to reproduce, most known viruses do *not* cause disease. Most viruses, including those that normally inhabit the human body, are harmless or are symbionts. Interestingly, viral genes from retroviruses comprise 8% of the human genome; some of these genes code for proteins essential to human life. Here we focus on viral infection of plants and animals.

Viruses cause serious plant diseases

Viruses cause many important plant diseases and are responsible for an estimated \$60 billion in agricultural

crop losses worldwide each year. Infected crops almost always produce lower yields and are less profitable than non-infected crops.

Viral infections do not usually kill plants, but they do stunt their growth; cause changes in the shape of the foliage; and may cause spots, streaks, or mottled patterns on leaves, flowers, or fruits (**FIG. 24-5**). Most plant viruses have capsids, but not envelopes. The genome of 75% of plant viruses consists of ssRNA. Plant viruses are typically named according to the type of host plant they infect and their effects on the plant. Tobacco mosaic virus, described at the beginning of this chapter, was the first virus ever discovered.

Insects are important vectors of plant disease. As they feed on plant tissues, aphids, leaf-hoppers, and many other insects spread viral diseases among plants. Some plant viruses can replicate within certain insects as well as in the host plant. These plant viruses may have originally existed in insects and evolved to replicate in plants. Some soil-borne nematodes and parasitic protozoa are vectors of viral infections in plant roots. They feed on infected roots and transmit the virus to surrounding roots.

Because plants have thick cell walls, viruses cannot penetrate plant cells unless the cells are damaged. Sap from virus-infected plants can be transmitted to healthy plants by injury from hands or agricultural equipment. Natural predation by animals can also transfer contaminated sap to healthy plants. About 20% of plant viruses can be transmitted from one generation to the next through infected seeds or pollen. Natural and artificial asexual propagation can also pass plant viruses to succeeding generations. Once a plant is infected, the virus spreads through the plant body by passing through *plasmodesmata*, cytoplasmic channels that connect adjacent plant cells. Some defenses against viral infection have evolved in plants. When a plant is injured, it reduces transport through the damaged plasmodesmata and quickly grows callus-like tissue, which covers the injured area. Plants can also mount a defense against viruses, called *RNA silencing*, using small interfering RNAs (siRNAs), which are stimulated in the presence of viral dsRNA. Unfortunately, plant viruses have evolved genes to code for proteins to repress the plant's defense.

There are no known cures for most viral diseases of plants, so infected plants are commonly burned. Vectors of plant virus transmission are controlled or eradicated following chemical or biological protocols. Many agricultural scientists are focusing their efforts on preventing viral disease by developing virus-resistant strains of important crop plants.

Viruses cause serious diseases in animals

Hundreds of different viruses infect animals, including humans. Animal viruses cause hog cholera, foot-and-mouth disease, canine distemper, avian influenza, and certain types

(b) Pepper leaves infected with tobacco mosaic virus. The leaf is characteristically mottled with light green areas.

Figure 24-5 Plant diseases caused by viruses

of cancer (such as feline leukemia and cervical cancer). In humans, viruses cause herpes simplex (one type causes genital herpes), mumps, rubella (German measles), rubeola (measles), warts, infectious mononucleosis, influenza, viral hepatitis, Ebola hemorrhagic fever, and AIDS (**TABLE 24-1** and *Inquiring About: Emerging Viruses*). Most humans suffer from two to six viral infections each year, including common colds and gastrointestinal disorders.

Norwalk virus is responsible for most worldwide viral gastroenteritis outbreaks and epidemics, affecting more than 200 million and killing more than 200,000 people each year. Norwalk virus is transmitted directly from person to person and indirectly by fecal contamination of water and food. The virus is also spread when infected people sneeze or cough, sending particles into the air; that is, virus particles become aerosolized. Infected individuals can shed viral particles for many weeks after symptoms abate. Norwalk virus infections are a serious concern, especially in closed communities, such as health care institutions, prisons, and cruise ships where people are in prolonged close contact. The genetically diverse strains of the Norwalk virus species make up the noroviruses.

Human activity, including social factors such as urbanization, global travel, immigration, and war, contributes to epidemics of infectious disease. Climate change increasingly impacts human health as mosquitoes and other vectors of viral infection expand their range into warmer areas (discussed in Chapter 57). As habitats expand and human travel facilitates greater movement, introduction and reintroduction of viruses and their carriers increases. Viruses such as Zika, chikungunya, and the virus that causes yellow fever continue to extend their range and become endemic in new parts of the world.

Living conditions, including sanitation, nutrition, physical stress, quality of health care, intravenous drug use, and sexual practices, are important factors in the spread of disease. In the United States and other, more developed countries, infectious disease accounts for about 4% to 8% of deaths compared with death rates of 30% to 50% in developing regions. Even at the level of our current knowledge about viruses and epidemiology, just how prepared are we to contain a particularly virulent virus? For example, how well are we containing HIV (the virus that causes AIDS), which continues to infect and kill millions of people worldwide every year?

Since the September 11, 2001, terrorist attacks in the United States, bioterrorism has become a critical concern worldwide. **Bioterrorism** is the intentional use of microorganisms or toxins derived from living organisms to cause death or disease in humans, animals, or plants on which humans depend. Terrorists could conceivably initiate epidemics of smallpox, anthrax, plague, yellow fever, Ebola hemorrhagic fever, and other potentially fatal diseases. (Note that anthrax and plague are caused by bacteria; see Table 25-4.) Rapid identification, effective treatments, and the development and deployment of vaccines for these diseases continue to be a critical global mission for scientists, health care officials, and governmental strategists.

Animal viruses have varied structure and life cycles

Most viruses cannot survive very long outside a living host cell. Their survival depends on being transmitted from one animal to another. However, their host range may be quite limited because attachment to a host cell is very specific.

The type of attachment proteins on the surface of a virus determines what type of cell it can infect. Receptors typically vary with each species and sometimes with each type of tissue. Thus, many human viruses can infect only humans because the viral attachment proteins combine only with receptor sites found on human cell membranes. The measles virus and poxviruses infect many types of human tissue because their attachment proteins combine with receptor sites on a variety of cells. In contrast, the poliovirus attaches to specific types of human cells, such as those that line the digestive tract and motor neurons of the brain and spinal cord.

Some viruses, such as the adenoviruses, have fibers that project from the capsid and adhere to complementary receptors on the host cell. Other viruses, such as those that cause herpes and rabies, are surrounded by a lipoprotein envelope

Table 24-1 Some Viruses That Infect Vertebrates

Group	Diseases Caused	Characteristics
DNA VIRUSES WITH ENVELOPE		
Herpesviruses	Cold sores (herpes simplex virus type 1); genital herpes, a sexually transmitted disease (herpes simplex virus type 2); chickenpox and shingles (herpes varicella-zoster virus); infectious mononucleosis and Burkitt's lymphoma (Epstein-Barr virus)	dsDNA ; medium to large, enveloped viruses; replicate in the host nucleus*
Poxviruses	Smallpox, cowpox, [†] monkeypox, and economically important diseases of domestic fowl	dsDNA ; large, complex viruses; replicate in the cytoplasm of the host cell
DNA VIRUSES WITH NO ENVELOPE		
Adenoviruses	Respiratory tract disorders (e.g., sore throat, tonsillitis), conjunctivitis, and gastrointestinal disorders are caused by more than 40 types of adenoviruses in humans; other varieties infect other animals	dsDNA ; replicate in the host nucleus
Papovaviruses	Human warts and some degenerative brain diseases; some cancers, including cervical cancer ^{‡‡}	dsDNA
Parvoviruses	Infections in dogs, swine, arthropods, rodents; gastroenteritis in humans (transmitted by consumption of infected shellfish)	ssDNA ; some require a helper virus to multiply
RNA VIRUSES WITH ENVELOPE		
Bunyaviruses	St. Louis encephalitis; hantavirus pulmonary syndrome (caused by Sin Nombre virus, a hantavirus)	ssRNA
Coronaviruses	Upper respiratory infections; SARS	ssRNA ; largest known RNA virus
Filoviruses	Hemorrhagic fever, including that caused by the Ebola virus	ssRNA
Flaviviruses	Yellow fever; West Nile infection; Zika virus infection; hepatitis C (the most common reason for liver transplants in the United States)	ssRNA
Orthomyxoviruses	Influenza (flu) in humans and other animals	ssRNA ; serve as a template for mRNA synthesis; medium-sized viruses that often exhibit projecting glycoprotein spikes
Paramyxoviruses	Rubeola (measles) and mumps in humans; distemper in dogs	ssRNA ; resemble orthomyxoviruses but somewhat larger
Retroviruses	AIDS; some types of cancer	ssRNA viruses that contain reverse transcriptase for transcribing the RNA genome into DNA; two identical molecules of ssRNA
Rhabdoviruses	Rabies	ssRNA
Togaviruses	Rubella (German measles)	ssRNA ; can serve as mRNA; large diverse group of medium-sized enveloped viruses; many transmitted by arthropods
RNA VIRUSES WITH NO ENVELOPE		
Noroviruses (made up of strains of Norwalk virus)	Most common cause of viral gastroenteritis in humans	ssRNA
Picornaviruses	Polio (poliovirus); hepatitis A (hepatitis A virus); intestinal disorders (enteroviruses); common cold (rhinoviruses); aseptic meningitis (coxsackievirus, echovirus)	ssRNA that can serve as mRNA; diverse group of small viruses
Reoviruses	Vomiting and diarrhea (rotaviruses); encephalitis (coltiviruses, orbiviruses)	dsRNA

* These viruses frequently cause latent infections; some cause tumors.

† The vaccinia (cowpox) virus is used to produce genetically engineered vaccines.

‡‡ The virus SV40 has been used as a vector to transport genes into cells.

with projecting glycoprotein spikes that attach to a host cell. The influenza virus has rodlike, glycoprotein spikes that project from its envelope. These spikes bind with specific receptors present only on cells lining the respiratory tract of certain vertebrates, including wild and domestic birds, horses, swine, and humans. Influenza vaccine prevents attachment by stimulating the host's antibodies to cover the glycoprotein spikes projecting from the virus.

Viruses have several ways to penetrate animal cells (**FIG. 24-6**). After attachment to a host-cell receptor, some enveloped viruses fuse with the animal cell's plasma membrane. The entire virus, including the capsid and nucleic acid, is released into the animal cell. Other viruses enter the host cell by *endocytosis*. In this process the plasma membrane of the animal cell invaginates, forming a membrane-enclosed vesicle that contains the virus. Endocytosis is advantageous

Inquiring About Emerging Viruses

An **emerging virus** is one that is new to a population or that is rapidly increasing in incidence. The best-known example is HIV, the virus that causes AIDS. Other emerging viruses include the coronavirus that causes severe acute respiratory syndrome (SARS); chikungunya, a viral disease transmitted by mosquitos; Ebola virus that causes hemorrhagic fever (see chapter-opening photograph); and Zika virus, which causes serious birth defects, including microcephaly (small brain). Many new, continual, or re-emerging pathogens appear suddenly and can strike globally.

Re-emerging viruses are those that have been almost eradicated and then suddenly recur, causing an epidemic, sometimes in a new geographic area. Many familiar diseases, such as influenza, malaria, tuberculosis, and bacterial pneumonias, continue to infect large numbers of people and increasingly reappear in forms that are resistant to drug therapy. Drug-resistant pathogens are a major challenge to public health and other health care professionals.

Historically, new viral strains have claimed many human lives. In 1918, for example, an influenza (flu) **pandemic** (global epidemic) killed more than 20 million people. Flu pandemics also occurred in 1957 and 1968. Each year new strains of influenza virus evolve and become infectious. If the new combination of viral genes is unfamiliar to the human immune system, the virus may spread easily, resulting in a pandemic. New strains of influenza are thought to infect one species, such as a species of birds. At first, they are not able to spread among mammals. However, because viruses can evolve, the avian strain can mutate and become virulent. The avian virus can also exchange RNA with a virus that has the genetic material necessary to spread among swine or other mammals. Swine can be susceptible to both avian and human strains of the virus. Inside a swine's body, the viruses can exchange bits of RNA and develop the ability to infect humans. When an animal disease crosses the species barrier and infects humans, it is called a **zoonotic disease**. (We discuss zoonosis further in Chapter 25.) Reassortment of genetic material can also occur inside a human host, producing a viral strain that can spread from person to person (see figure). H1N1 influenza evolved in this way.

An influenza virus such as H1N1 evolves as it mutates and its RNA reassorts in the bodies of birds, swine, and humans. Eventually, it becomes virulent.

to the virus because the endocytotic vesicle delivers the virus deep into the cytosol.

In DNA animal viruses, replication of viral DNA and protein synthesis are similar to the processes by which the host cell would normally carry out its own DNA replication and protein synthesis. In most RNA viruses, RNA synthesis takes place with the help of an RNA-dependent RNA polymerase.

Retroviruses are RNA viruses that have a DNA polymerase called **reverse transcriptase**, which transcribes the RNA genome into a DNA intermediate (FIG. 24-7). This DNA

becomes integrated into the host DNA by an enzyme also carried by the virus. Copies of the viral RNA are synthesized as the incorporated DNA is transcribed by host RNA polymerases. The **human immunodeficiency virus (HIV)** that causes AIDS is a retrovirus. Some retroviruses can cause cancer directly or by interacting with other cancer-causing viruses.

After viral genes are transcribed, the viral structural proteins are synthesized. The capsid is produced, and then assembly of new virus particles takes place. Finally, release occurs. Viruses that do not have an outer envelope exit by

Key Point

Viruses bind to specific receptor proteins on the animal cell's plasma membrane. Enveloped viruses then enter the cell by membrane fusion.

Figure 24-6 Viral infection in animals

CONNECT Why can't new viruses be completely assembled in the nucleus of the host?

cell lysis. The plasma membrane ruptures, releasing many new viral particles. Enveloped viruses obtain their lipoprotein envelopes by picking up a fragment of the host plasma membrane as they leave the infected cell (see Figs. 24-6b and 24-7).

Viral proteins damage the host cell in several ways. These proteins may alter the permeability of the plasma membrane

or may inhibit synthesis of host nucleic acids or proteins. Viruses sometimes damage or kill their host cells by their sheer numbers. A poliovirus can produce 100,000 new viruses within a single host cell!

Viruses quickly become resistant to antiviral drugs
Antibiotics are specific for fighting bacteria; they do not kill

Retroviruses use reverse transcriptase to transcribe their RNA into DNA; the viral DNA becomes part of the host DNA. When activated, viral DNA uses host enzymes to transcribe viral RNA.

Figure 24-7 Life cycle of HIV, the retrovirus that causes AIDS

HIV infects T helper cells, specialized cells of the host's immune system. The virus attaches to protein receptors, known as CD4, on the plasma membrane of T helper cells. HIV has two identical single-stranded RNA molecules.

CONNECT What advantage does the retrovirus that causes AIDS have compared to an RNA virus?

viruses. Fortunately, researchers continue to develop antiviral drugs. These drugs are currently used to treat many diseases, including HIV, hepatitis B and C, herpes, and influenza A and B.

Antiviral drugs do not typically destroy viruses. Rather, they inhibit the development, or replication, of many types of RNA and DNA viruses. Unfortunately, viruses rapidly

develop resistance, making antiviral drug design and therapy a constantly changing, competitive endeavor. For example, amantadine, which inhibits penetration or uncoating of viral nucleic acids, had been effective in treating patients with influenza. Unfortunately, most strains of influenza virus have become resistant to amantadine, perhaps as a result of common use of the drug in poultry feed in certain areas of Asia, such as China.

Another type of antiviral drug (e.g., Tamiflu) inhibits a viral enzyme (neuraminidase) necessary for the virus to leave the host cell. Certain viral strains are becoming resistant to Tamiflu. A single mutation that occurs spontaneously is apparently responsible for this resistance. New antiviral drugs are being designed or are currently in clinical trials. Some inhibit viral attachment to host cells, and others interfere with replication of viral nucleic acid.

Viruses are being genetically modified to treat diseases such as cancer. Viruses can be reprogrammed to enter, reproduce, and destroy cancer cells. For example, researchers have deleted a replication gene from herpes simplex virus and replaced it with a human gene that stimulates immunity. This virotherapy procedure is now being used to destroy melanoma, a type of skin cancer. Researchers are developing strategies using RNA-targeted CRISPR to target and inhibit the hepatitis C virus (a ssRNA virus) in cells. Ongoing research suggests that these strategies may be effective against several other viruses, including HIV.

- What are the mechanisms by which viruses enter animal cells?
- **VISUALIZE** Draw a diagram illustrating how retroviruses, such as HIV, make copies of themselves.

24.5 Evolution of Viruses

LEARNING OBJECTIVE

- 8 Trace the evolutionary origin of viruses according to current hypotheses and describe research regarding the evolution of polydnaviruses.

Scientists have been debating the origin of viruses ever since they were discovered. Currently, there are three main hypotheses: the progressive (or escape) hypothesis, the regressive (or reduction) hypothesis, and the virus-first hypothesis.

According to the *progressive hypothesis*, also known as the *escape hypothesis*, viruses may have originated as mobile genetic elements such as *transposons* (see Chapter 13) or plasmids (small, circular DNA fragments discussed in

Chapters 15 and 25). Such fragments could have escaped from one cell and entered another cell through damaged cell membranes. According to this hypothesis, the origin of viruses may be traced back to archaeal, bacterial, protist, plant, or animal cells. Their multiple origins may explain why many viruses are species specific; perhaps they infect only those species that are closely related to the organisms from which they originated. This hypothesis is supported by the genetic similarity between some viruses and their host cells—a closer similarity than exists between one type of virus and another.

The *regressive hypothesis*, also called the *reduction hypothesis*, asserts that viruses are remnants of cellular organisms and evolved from small cells that were parasites in larger cells. Genes that they did not need, like those for protein synthesis, were gradually lost through evolution. This hypothesis is supported by certain bacteria (chlamydia and rickettsia) that are able to reproduce only inside the cells of their hosts (see Table 25-4).

The regressive hypothesis is also supported by the discovery that some giant viruses have genes that code components for protein translation. Proponents of the regressive hypothesis suggest that these giant viruses evolved from a free-living, complex cellular ancestor. Later, they became parasitic and gradually lost some of the genes necessary for protein synthesis. This hypothesis explains how viruses could have existed before their present-day hosts evolved.

The *virus-first hypothesis* states that viruses predate or coevolved with their current cellular hosts even before the life-forms assigned to the three domains diverged. One research team recently suggested that viruses initially existed in a pre-cellular world as self-replicating units. Gradually, these small units became more organized and more complex. Eventually they evolved to produce enzymes for the synthesis of membranes and cell walls, leading to the origin of the first cells.

Evidence for this hypothesis comes from similarities found in the protein structures of some viral capsids and in genetic similarities between some viruses that infect archaea and some that infect bacteria. Molecular biologists studying this hypothesis consider it improbable that these similarities evolved independently. They hypothesize that viruses diverged very early—before archaea, bacteria, or eukaryotes.

Recent studies on the origin of polydnaviruses contribute to our understanding of viral evolution. **Polydnaviruses** are particles that consist of multiple circles of dsDNA encased in capsid proteins and an envelope. Each circle of DNA contains part of the virus genome. These viruses are found in ovary cells of many species of parasitic wasps. The polydnaviruses are unusual in that their circular DNA does not have genes for making the proteins needed to replicate and produce new viruses. Genes needed for these viruses to replicate are found only in the wasp genome; the viruses can replicate only in the wasp ovary cells.

The wasp injects polydnaviruses along with her eggs into certain caterpillars. The polydnaviruses express toxins that

interfere with the caterpillar's immune defenses and development. The wasp eggs hatch and develop inside the caterpillar. The young wasps feed on the caterpillar.

Biologists wondered whether the polydnaviruses were really viruses. Were the polydnaviruses simply particles derived from wasp genes? An alternative hypothesis was that millions of years ago a particular virus infected wasps. The virus genome became integrated into the wasp genome and lost the capacity to enter virus particles. Instead, wasp DNA was incorporated into the particles. Read the Key Experiment, **FIGURE 24-8**, to learn which hypothesis is supported by the research of Jean-Michel Drezen, Annie Bézier, and their colleagues.

Today's viruses may have originated multiple times, through many mechanisms, or by a mechanism not yet discovered. No matter how viruses came to be and how they continue to evolve, they have important roles in evolution. They mutate constantly, producing many new alleles. They replicate rapidly, and some of their genes are incorporated into the genomes of host cells through horizontal gene transfer. In fact, viruses can provide a major source of new genes for their host cells.

CHECKPOINT 24.5

- **CONNECT** How could viruses have evolved before their hosts? Explain your answer.
- **CONNECT** In what way are polydnaviruses mutualistic partners with certain wasps?

24.6 Subviral Agents

LEARNING OBJECTIVE

- 9 Compare satellites, viroids, prions, and defective interfering particles (DIPs).

Subviral agents are infective agents that are smaller and simpler than viruses. Subviral agents include satellites, viroids, prions, and defective interfering particles (DIPs).

Satellites depend on helper viruses

Satellites are subviral agents that depend on co-infection of a host cell with a helper virus. The satellite, which consists of either DNA or RNA, cannot reproduce without the helper virus. A satellite is called a satellite virus when the satellite encodes the coat protein in which it is encapsulated.

Sputnik is a satellite that infects *Mimivirus*, which in turn infects an amoeba. Sputnik is dependent on the replication and assembly machinery set up by Mimivirus. Many researchers now refer to Sputnik as a *virophage*. The term implies that Sputnik, and perhaps other satellites, impair the reproduction of Mimivirus, its helper virus.

What is the origin of polydnaviruses?

HYPOTHESIS: Polydnaviruses evolved from ancient viruses that infected wasps.

EXPERIMENT: Annie Bézier, Jean-Michel Drezen, and their colleagues searched for virus-related genes in the wasp genome. The team analyzed DNA from three different wasp species. They compared nucleotide sequences with sequences of public databases containing sequences of all organisms and viruses studied.

RESULTS AND CONCLUSION: The researchers identified 22 genes expressed in wasp ovaries where viral particles are produced. These genes are present in the wasp genome and resemble key genes of nudiviruses, a family of insect viruses. The investigators found that many of these genes code for proteins that are part of the polydnavirus particles. These genes have been conserved in several different wasp families that have polydnaviruses.

The research team concluded that the polydnavirus evolved from a nudivirus that infected wasps millions of years ago. In time, the virus genome became incorporated into the wasp genome. Proteins needed for viral replication are now part of the wasp's DNA, and the virus can replicate only in the wasp's ovaries.

At the same time, the wasps depend on the virus. The wasps inject their eggs into certain caterpillars along with polydnaviruses. The viruses depress the caterpillar's immune defenses, allowing the wasp larvae to develop in the caterpillar. Thus, a mutualistic relationship has evolved between the wasp and the polydnavirus.

The investigators suggested that the polydnavirus acts as a gene vector, transporting large chunks of DNA to the caterpillar. Might learning more about this mechanism have clinical applications?

SOURCE: Bézier, Annie, et al., "Polydnaviruses of Braconid Wasps Derive from an Ancestral Nudivirus," *Science*, Vol. 323, No. 5916 (Feb. 13, 2009): 926–930.

Figure 24-8 Exploring the evolution of polydnaviruses

This TEM shows polydnavirus particles in the nucleus of a cell in a wasp ovary. The polydnavirus particles are located at the periphery of an electron-dense region thought to be a "viral factory."

PREDICT What would happen if the polydnavirus mutated and no longer depressed the caterpillar's immune defenses?

Viroids are short, single strands of naked RNA

In 1971, Theodor Otto Diener, a plant pathologist, discovered an infective agent in potatoes that he named a **viroid**. Since then, more than 30 species of viroids have been identified. Smaller than a virus, a viroid consists of a very short, circular, single strand of naked RNA (only 250 to 400 nucleotides). The viroid has no protective protein coat and no associated proteins to assist in duplication. Its RNA serves as a template that is copied by host RNA polymerases. Viroids are extremely hardy and can resist heat and ultraviolet radiation because of the condensed folding of their RNA. Until recently it was thought that viroids only infect plants. However, it is now known that a viroid enclosed in a hepatitis B virus capsid causes the human disease hepatitis D.

Many viroids that cause plant diseases—including potato spindle tuber viroid, apple scar skin viroid, avocado sunblotch viroid, and tomato chlorotic dwarf viroid—have been identified. Viroids cause stunted or distorted growth and sometimes kill the plant. For example, cadang-cadang disease has killed more than 30 million coconut palm trees in the Philippines. Viroids are transmitted by infected pollen or seeds.

Viroids are generally found within the host-cell nucleus and appear to interfere with gene regulation. Molecular biologists have hypothesized that viroids mirror gene sequences in their hosts and silence critically important host genes. The viroid's ssRNA replicates, forming dsRNA. The plant's defense response cleaves this viroid RNA, producing small interfering RNAs (siRNAs), discussed in Chapters 13 and 14. However, the viroid siRNAs then cause host ribonucleases to selectively cleave host mRNAs with complementary base sequences. This action inactivates host mRNA and silences specific host genes. The viroids themselves are resistant to RNA silencing.

Prions are protein particles

Motivated by the death of a patient from Creutzfeldt–Jakob disease (CJD), a degenerative brain disease, Stanley Prusiner, professor of neurology and biochemistry at the University of California, San Francisco, began his studies of prions in the early 1970s. Prusiner discovered that the infective agent was not affected by radiation (which typically mutates nucleic acids), and he could not find DNA or RNA in the particles. In 1982, he named the infective agent **prion**, for “proteinaceous infectious particle.”

Prusiner's hypothesis that an infectious agent could cause disease without nucleic acids was not readily accepted because there was no known mechanism by which this action could occur. However, Prusiner and other researchers continued to study prions and discovered how they can cause cells to malfunction. In 1997, Prusiner was awarded the Nobel Prize in Physiology or Medicine for his discovery of prions.

Prusiner and others have shown that animals have a gene that encodes a normally harmless protein known as PrP. Normal forms of the protein are found on the surfaces of brain

cells and many other types of cells. The PrP protein, which consists of 208 amino acids, helps neurons transport copper and may play a role in the sense of smell in animals. Researchers have discovered that normal PrP interacts with the peptides associated with Alzheimer's disease.

Sometimes, the PrP protein folds into a different shape, an insoluble form that can cause disease. This misfolded protein is the prion. Mutations in the gene that encodes the PrP protein increase the risk that the protein will misfold and become a prion. The prion then somehow induces other PrP molecules to misfold into the pathogenic form (**FIG. 24-9**). Prions apparently can aggregate and accumulate in the brain and in certain other tissues and cause serious damage.

Prions are found in the brains of patients with *transmissible spongiform encephalopathies* (TSEs). This group of fatal degenerative brain diseases has been identified in birds and mammals. These diseases are called TSEs because when infected, the brain appears to develop holes and becomes somewhat spongelike. The TSEs are in some ways like viral illnesses. However, there is a long latency period (about 5 years in cows and up to 10 years in humans) between contracting the infection and developing symptoms of the illness. Also, the TSEs have proven very difficult to treat. Genetically engineered mice that lack the prion protein gene are immune to TSE infection.

Figure 24-9 A model for how prion populations expand. Prions contact normal PrP proteins and induce them to misfold and become prions. Each new prion can then contact additional PrP molecules and induce them to misfold, thus expanding the prion population. Prions can form clumps by aggregating.

The oldest known prion disease is *scrapie* in sheep and goats. When infected, animals lose coordination, become irritable, and itch so severely that they scrape off their wool or hair. Bovine spongiform encephalopathy (BSE) is a related prion disease popularly referred to as “mad cow disease” because some diseased cattle become aggressive. In the 1990s, BSE became epidemic in cattle in the United Kingdom.

More than 200 people have died from a human variety of BSE, providing evidence that the disease is transmissible from cow to human. The human disease is called vCJD because it is a variant of CJD, which is caused by the transformation of PrP proteins into prions. The infectious agent of vCJD has been recovered from infected human neural tissue and appears similar to the prion that causes scrapie in sheep. New regulations have been instituted in many countries to safeguard the food supply. Human-to-human transmission of vCJD has been associated with tissue and organ transplants and with transfusion with contaminated blood.

Chronic wasting disease, an illness related to mad cow disease, has spread among deer and elk populations in North America. Studies are under way to determine whether chronic wasting disease can infect livestock or humans. In 2015 researchers in Texas discovered that plants can act as a vector for prions when they attach to a plant and the plant is then consumed. Feline spongiform encephalopathy is a prion disease of domestic and captive felines. With this disease, large deposits of a misfolded protein accumulate in the liver and spleen.

Like viruses, prions exhibit variability. Different strains of prions may differ from one another in the conformation of their proteins, in their properties, and in the diseases they cause. Prions are different from viruses in that they can arise spontaneously, mostly as a result of mutation. Researchers are studying ways to block prions from forming. They are also looking for ways to stimulate cells to destroy prions. Early diagnosis is critical, and the search for an assay, or test, to detect prion disease is ongoing.

Defective interfering particles are virus mutants

Defective interfering particles (DIPs) are naturally occurring viral mutants that are spontaneously generated when part of the viral genome is lost due to defective replication. DIPs can only penetrate a host cell when accompanied by a helper virus. DIPs can occur in all types of DNA and RNA viruses. The particles compete with non-defective viruses, which is why they are called “interfering.” DIPs are being studied as a possible virus therapy. Researchers have used DIPs to make a “protecting virus,” which rendered influenza A non-lethal in research with mice.

CHECKPOINT 24.6

- **CONNECT** What do viroids and prions have in common? How are they different?

Summary: Focus on Learning Objectives

24.1 The Status and Structure of Viruses (page 500)

1 Contrast a virus with a cellular organism.

- A **virus** is a very small infective agent that consists of a core of nucleic acid and is dependent on a living host. Viruses contain the nucleic acids necessary to make copies of themselves, but to reproduce they must invade living cells and commandeer their metabolic machinery.

2 Describe the structure of a virus.

- A virus is a subcellular particle consisting of a DNA or RNA genome surrounded by a protein coat, called a **capsid**. In some viruses the capsid is surrounded by an outer envelope.

24.2 Classification of Viruses (page 502)

3 Identify three characteristics used to classify viruses.

- Viruses are classified based on **host range**, the types of host species they can infect; the type of nucleic acid they contain; and whether the nucleic acid is single-stranded or double-stranded. Other factors used to classify viruses include size and shape, presence of an envelope, and method of transmission from host to host.

24.3 Viral Replication (page 503)

4 Characterize bacteriophages.

- Bacteriophages**, or **phages**, are complex viruses that infect bacteria. They typically consist of a long molecule of dsDNA coiled within a polyhedral head.

5 Contrast a lytic cycle with a lysogenic cycle.

- In a **lytic cycle**, the virus destroys the host cell. The five steps in a lytic cycle are *attachment* to the host cell, *penetration* of viral nucleic acid into the host cell, *replication* of the viral nucleic acid, *assembly* of newly synthesized components into new viruses, and *release* from the host cell.
- The nucleic acid of some phages becomes integrated into the DNA of its bacterial host. The phage is then called a **prophage**. A **temperate virus** alternates between a lytic and a lysogenic cycle. In a **lysogenic cycle**, the genome of a temperate virus is replicated along with replication of the host's DNA without causing death of the host cell.

- Bacterial cells that carry prophages are lysogenic cells. In **lysogenic conversion**, bacterial cells containing certain temperate viruses exhibit new properties.

24.4 Viral Diseases (page 504)

6 Contrast viral infection of plants and animals, and identify specific diseases caused by viruses.

- Most plant viruses are ssRNA viruses that do not have envelopes. Plant viruses penetrate plants through damaged cells and are also transmitted by infected seeds. Viruses can be spread among plants by insect vectors. Viruses spread through the plant via plasmodesmata.
- Viruses enter animal cells by membrane fusion or by endocytosis. Diseases caused by DNA viruses include herpes, respiratory infections, and gastrointestinal disorders. RNA viruses cause influenza, upper respiratory infections, AIDS, and some types of cancer.

7 Describe the reproductive cycle of a retrovirus, such as human immunodeficiency virus (HIV).

- Retroviruses**, such as HIV, use **reverse transcriptase** to transcribe their RNA genome into a DNA intermediate that becomes integrated into the host DNA. Copies of the viral RNA are then synthesized.

24.5 Evolution of Viruses (page 511)

8 Trace the evolutionary origin of viruses according to current hypotheses and describe research regarding the evolution of polydnaviruses.

- According to the *progressive*, or *escape*, *hypothesis*, viruses may have originated as mobile genetic elements that could have escaped and moved from one cell and entered another through damaged cell membranes. Viruses may trace their origin to animal cells, plant cells, bacterial cells, or archaeal cells.
- The *regressive*, or *reduction*, *hypothesis* asserts that viruses are remnants of cellular organisms; they evolved from free-living, complex cellular ancestors. As they became parasitic, some of the genes necessary for protein synthesis were lost through evolution. According to the *virus-first hypothesis*, viruses predate or coevolved with their current cellular hosts. Viruses may have initially existed as self-replicating units. As they evolved, viruses produced enzymes for the synthesis of membranes and cell walls, leading to the formation of the first cells.
- Evidence suggests that **polydnaviruses** evolved from viruses that infected wasps. They have become mutualistic partners with their wasp hosts.

24.6 Subviral Agents (page 512)

9 Compare satellites, viroids, prions, and defective interfering particles (DIPs).

- Satellites, viroids, and prions are smaller than viruses. Satellites reproduce only with the help of a helper virus. A **viroid** consists of a short strand of RNA with no protein coat. Many viroids cause plant diseases.
- A **prion** consists only of protein. Prions cause fatal degenerative brain diseases, such as *transmissible spongiform encephalopathies (TSEs)*. A **DIP** can only penetrate a host cell accompanied by a helper virus.

Test Your Understanding

Know and Comprehend

1. The genome of a virus consists of (a) DNA (b) RNA (c) prions (d) DNA and RNA (e) DNA or RNA
2. The capsid of a virus consists of (a) protein subunits (b) nucleic acid (c) helical lipids (d) a carbohydrate envelope (e) RNA and lipid
3. Viruses that kill host cells are (a) lysogenic (b) lytic (c) viroids (d) prophages (e) temperate
4. In lysogenic conversion, (a) bacterial cells may exhibit new properties (b) the host cell dies (c) prions sometimes convert to viroids (d) reverse transcriptase transcribes DNA into RNA (e) lytic viruses become temperate
5. The types of host species a particular virus can infect are referred to as its (a) assembly (b) commensal cohort (c) host range (d) prophage factor (e) virulence factor
6. Plant viruses (a) typically cause rapid death of infected plants (b) are mainly retroviruses (c) can be killed with antibiotics (d) are transmitted throughout the plant body by insects (e) can be transmitted from one generation to the next through infected seeds
7. According to the progressive, or escape, hypothesis, viruses (a) appeared before the three domains diverged (b) came from mobile genetic elements and had multiple origins (c) evolved from early plant cells (d) are bits of nucleic acid that escaped from animal cells (e) evolved from cells that were parasites in larger cells
8. Prions (a) consist of RNA with no protein coat (b) are misfolded proteins (c) cause several important plant diseases (d) are the infective agents of several emerging diseases (e) consist of proteins that stimulate host RNA to produce DNA

Apply and Analyze

9. Arrange the following list into the correct sequence for viral reproduction: 1. penetration 2. assembly 3. replication 4. attachment 5. release (a) 1, 2, 3, 4, 5 (b) 5, 2, 3, 4, 1 (c) 4, 1, 3, 2, 5 (d) 4, 1, 2, 3, 5 (e) 3, 1, 2, 4, 5

10. Arrange the following list into the correct sequence for part of the cycle of a retrovirus: 1. dsDNA integrated into host DNA 2. viral proteins synthesized on host ribosomes 3. viral DNA uses host enzymes to transcribe viral RNA 4. reverse transcriptase catalyzes synthesis of ssDNA 5. synthesis of second DNA strand (a) 5, 2, 1, 3, 4 (b) 5, 2, 3, 4, 1 (c) 4, 5, 1, 3, 2 (d) 4, 1, 2, 3, 5 (e) 2, 1, 3, 4, 5
11. **VISUALIZE** What does this diagram illustrate? Complete the labels.

12. **CONNECT** How are viral genomes different from those of plant or animal cells?
13. **CONNECT** How do viroids and prions differ from viruses?

Evaluate and Synthesize

14. **EVOLUTION LINK** Discuss the coevolution of polydnaviruses and their mutualistic partners. (See the discussion and Key Experiment on polydnaviruses.)
15. **EVOLUTION LINK** Based on what you have learned about viruses, present an argument for one of the three hypotheses of virus origin.
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** What is the continuous challenge that the influenza virus presents to scientists and public health officials? How can they use technology and work together to meet this challenge?

25 Bacteria and Archaea

In this chapter we examine the diversity and characteristics of the members of domain Bacteria and domain Archaea, two of the three main branches of the tree of life. These organisms, informally called prokaryotes, have inhabited our planet for more than 3.5 billion years, much longer than eukaryotes, which evolved about 2.2 billion years ago. Although prokaryotes are microscopic, they are so numerous that they probably account for more than half of Earth's biomass, the mass of living material. Thus, the biomass of prokaryotes is greater than that of all the eukaryotes: fungi, plants, and animals. As scientists discover new prokaryotes and explore new niches and habitats, the percentage of bacteria and archaea in the Earth's total biomass continues to increase.

Anton van Leeuwenhoek, a Dutch microscopist, discovered bacteria and other microorganisms in 1674 when he looked at a drop of lake water through a glass lens. During the late 1800s, many microorganisms, including some bacteria, fungi, and protozoa, were identified as **pathogens**, agents that cause disease. Bacteria cause many diseases, such as tuberculosis, tetanus, respiratory infections, and food poisoning in humans. However, only a small minority of bacterial species are pathogens. (Although some archaea have been associated with disease, no pathogenic archaea have been identified.)

Both bacteria and archaea play essential roles in the biosphere. As decomposers they break down organic molecules into their components. Along with fungi, prokaryotes are nature's chief recyclers. Without these microorganisms, elements such as carbon, nitrogen, phosphorus, and sulfur would remain locked

KEY CONCEPTS

- 25.1** Bacteria and archaea are single-celled organisms; their prokaryotic cells do not have membrane-enclosed organelles; most have a cell wall that surrounds the plasma membrane; and most have a single, circular DNA molecule.
- 25.2** Evolution occurs rapidly in prokaryotes; natural selection acts on the genetic variation provided by mutations and genetic recombination and is facilitated by rapid reproduction.
- 25.3** The great diversity that has evolved in their metabolism and mode of nutrition allows prokaryotes to thrive in all kinds of habitats.
- 25.4** Prokaryotes make up two of the three domains: Bacteria and Archaea.
- 25.5** Prokaryotes form intimate relationships with other organisms and play critical roles in ecology, commerce, and technology.
- 25.6** The many adaptations that have evolved in pathogenic bacteria contribute to their great success.

PHOTO: *Oscillatoria*, a genus of cyanobacteria that forms unbranched filaments. Cyanobacteria are the only prokaryotes that carry on photosynthesis that generates oxygen. NASA plans to use cyanobacteria, along with algae, to produce the oxygen that is needed in the upcoming mission to send humans to Mars.

Michael Abbey/Visuals Unlimited, Inc.

up in the wastes and dead bodies of plants, animals, and other organisms and would be unavailable for the synthesis of new cells and organisms.

One group of prokaryotes, the cyanobacteria, are producers that carry on photosynthesis, which generates oxygen (see photograph). In fact, 70% to 80% of the oxygen on planet Earth is generated by cyanobacteria and algae. Other prokaryotes convert atmospheric nitrogen to ammonia and then to nitrates, forms that are used by plants (see Fig. 55-8). This conversion enables plants and animals (because they eat plants) to manufacture essential nitrogen-containing compounds such as proteins and nucleic acids.

We begin this chapter with a description of the structure of bacteria and archaea, and then we discuss prokaryote reproduction and evolution. We outline some of the nutritional and metabolic adaptations of these organisms and describe the phylogeny of the two prokaryote domains. We then present an overview of prokaryote relationships with other organisms and the effect of prokaryotes on ecology, technology, and commerce. We end the chapter with a discussion of bacteria and disease.

25.1 The Structure of Bacteria and Archaea

LEARNING OBJECTIVES

- 1 Describe the structure and common shapes of prokaryotic cells.
- 2 Compare the bacterial cell wall in gram-positive and gram-negative bacteria.
- 3 Describe movement in prokaryotes and describe the structure of the bacterial flagellum.

In contrast to viruses, viroids, and prions, which consist only of nucleic acid and/or protein, **prokaryotes**, assigned to domain Archaea or Bacteria, are cellular organisms. However, recall from Chapters 4 and 23 that the cell structure of prokaryotes is fundamentally different from that of the eukaryotic cells of other living organisms.

Most prokaryotic cells are very small. Typically, their diameter ranges from 0.5 to 1.0 μm , and their length ranges from 1.0 to 5.0 μm . Their cell volume is only about one-thousandth that of small eukaryotic cells, and their length is only about one-tenth. Most prokaryotes are unicellular, but some form colonies or filaments containing specialized cells.

Prokaryotes have several common shapes

Three common prokaryote shapes are spherical, rod-shaped, and spiral. Spherical prokaryotes, known as **cocci** (sing., *coccus*), occur singly in some species and in groups of independent cells in others (**FIG. 25-1a**). Cells may be grouped in twos (*diplococci*), in long chains (*streptococci*), or in irregular clumps that look like bunches of grapes (*staphylococci*). Rod-shaped prokaryotes, called **bacilli** (sing., *bacillus*), may occur as single rods or as long chains of rods (**FIG. 25-1b**). Some prokaryotes form spirals. If the spiral-shaped cell is flexible, it is a **spirochete**; if rigid, it is a **spirillum** (pl., *spirilla*) (**FIG. 25-1c**). A spirillum shaped like a comma is called a **vibrio**. Some archaea have unusual shapes, such as triangular or square-shaped cells.

Prokaryotic cells do not have membrane-enclosed organelles

In contrast to eukaryotic cells, prokaryotic cells do not have a nucleus or other membrane-enclosed organelles (**FIG. 25-2**; see Chapter 4). Although the prokaryotic cell does not have a membrane-enclosed nucleus, it does have a **nuclear area**, also referred to as the **nucleoid**, which contains DNA.

The dense cytoplasm of the prokaryotic cell contains ribosomes (smaller than those found in eukaryotic cells) and storage granules that hold glycogen, lipid, and phosphate compounds. Enzymes needed for metabolic activities may be located in the cytoplasm. Although the membranous organelles of eukaryotic cells are absent, in some prokaryotic cells the plasma membrane is extensively folded inward. Enzymes needed for cellular respiration and photosynthesis may be associated with the plasma membrane or its folds.

(a) **Cocci bacteria.** Colorized SEM of *Staphylococcus aureus*. These cocci cause skin and wound infections, food poisoning, and toxic shock syndrome.

(b) **Bacilli bacteria.** Colorized SEM of *Salmonella*. These bacilli cause food poisoning.

(c) **Spirochete bacteria.** Colorized SEM of *Borrelia burgdorferi*. These spirochetes cause Lyme disease, transmitted by infected deer ticks.

Figure 25-1 Common shapes of prokaryotes

Key Point

In contrast to eukaryotic cells, prokaryotic cells lack organelles enclosed by membranes; the DNA is not surrounded by a nuclear envelope.

Figure 25-2 Structure of a prokaryotic cell

This bacillus is a gram-negative bacterium (discussed in text). Prokaryotic cells typically have a nuclear area with a single, circular DNA molecule. They may also have one or more plasmids, small rings of DNA that replicate independently.

PREDICT Why might the absence of a nucleus be an advantage for prokaryotes?

A cell wall protects most prokaryotes

Most prokaryotic cells have a **cell wall** surrounding the plasma membrane. The cell wall provides a rigid framework that supports the cell and maintains its shape. Bacterial cells have a high concentration of dissolved solutes. The cell wall keeps the cell from bursting under hypotonic conditions (see Chapter 5). Thus, most bacteria are adapted to hypotonic surroundings. When wall-less forms of bacteria are produced experimentally, they must be maintained in isotonic solutions to keep them from bursting. However, cell walls are of little help when a bacterium is in a hypertonic environment, as in food preserved by a high sugar or salt content. For this reason, most bacteria grow poorly in jellies, jams, salted fish, and other foods preserved in these ways.

The bacterial cell wall includes **peptidoglycan**, a complex polymer that consists of two unusual types of sugars (amino

sugars) linked with short polypeptides. The sugars and polypeptides are cross-linked to form a crystalline lattice that surrounds the entire plasma membrane. Peptidoglycan is absent in the archaeon cell wall.

Differences in bacterial cell wall composition are of great interest to microbiologists and are important clinically. In 1888, Danish physician Christian Gram developed the Gram staining procedure. Bacteria that absorb and retain crystal violet stain in the laboratory are referred to as **gram-positive bacteria**. Bacteria that do not retain the stain when rinsed with alcohol are **gram-negative bacteria**. The cell walls of gram-positive bacteria are very thick and consist primarily of peptidoglycan. The cell walls of gram-negative bacteria have two layers: a thin peptidoglycan layer and a thick outer membrane. The outer membrane resembles the plasma membrane but contains polysaccharides bonded to lipids (**FIG. 25-3**).

(a) **Gram-positive cell wall.** A thick layer of peptidoglycan molecules is held together by amino acids.

(b) **Gram-negative cell wall.** A thin layer of peptidoglycan is covered by an outer membrane.

Figure 25-3 Bacterial cell walls

If present, the capsule (shown only in the locator cells) is outside the cell wall.

Distinguishing between gram-positive and gram-negative bacteria is important in treating certain diseases. For example, the antibiotic penicillin interferes with peptidoglycan synthesis, ultimately resulting in a fragile cell wall that cannot protect the cell (see Chapter 7 discussion of drugs that are enzyme inhibitors). Predictably, penicillin works most effectively against gram-positive bacteria.

Some bacteria produce capsules or slime layers

Many prokaryote species produce a **capsule** or **slime layer** that surrounds the cell wall. A slime layer is more loosely attached to the cell wall than a capsule. These outer layers are made of polysaccharide or protein.

In free-living species, the outer covering may provide the cell with added protection against phagocytosis (engulfment; see Chapter 5) by other microorganisms. In disease-causing bacteria, a capsule or slime layer may protect against phagocytosis by the host's white blood cells. The ability of *Streptococcus pneumoniae* to cause bacterial pneumonia depends on its capsule. A strain of *S. pneumoniae* that lacks a capsule does not cause the disease. Bacteria also use their capsules to attach to surfaces such as rocks, plant roots, and human teeth (where they cause dental plaque).

Some prokaryotes have fimbriae or pili

Some prokaryotes have hundreds of hair-like appendages called **fimbriae** (sing., *fimbria*). Fimbriae, which are made of protein, are shorter than flagella. **Pili** (sing., *pilus*) are usually longer than fimbriae. There are typically fewer pili on the cell surface than fimbriae. Prokaryotes use fimbriae and pili to attach to cell surfaces and, in the case of pathogenic bacteria, to the surfaces of cells they infect. These protein structures also help bacteria adhere to one another. Some elongated pili, called *sex pili*, are important in transmitting DNA between bacteria.

Some bacteria survive unfavorable conditions by forming endospores

When the environment becomes unfavorable—for example, when nutrients are limited or the environment becomes very dry or hot—some types of bacteria produce extremely durable, dormant cells called **endospores**. To form an endospore, the bacterial cell divides by binary fission, forming a large cell that surrounds a smaller cell containing the genome. After an endospore forms, the cell wall of the original cell disintegrates, releasing the endospore.

Endospores survive in very dry, hot, or frozen environments or at times when food is scarce. Some endospores are so resistant that they can survive an hour or more of boiling or centuries of freezing. When environmental conditions are again suitable for growth, the endospore germinates, forming an active, growing bacterial cell.

Several types of bacteria that form endospores cause disease (**FIG. 25-4**). The endospore of *Bacillus anthracis*, the bacterium that causes anthrax, is so hardy that this pathogen has become a concern as an agent of biological warfare. The bacteria (*Clostridium tetani*) that cause tetanus and the bacteria (*C. perfringens*) that cause gas gangrene typically enter the body with soil when a person suffers a deep cut or puncture wound. Patients may also be exposed to these serious diseases when surgical instruments are not effectively sterilized, allowing endospores to survive.

Formation of endospores is not a type of reproduction in bacteria; endospores are not comparable to the reproductive spores of fungi and plants. Only one endospore is formed per original

Figure 25-4 Endospores

Color-enhanced TEM of *Clostridium tetani*, the bacterium that causes tetanus. Each bacterial cell (blue) contains one endospore (orange), a resistant, dehydrated cell that develops within the original cell.

cell, so the total number of individuals does not increase. Archaea do not form endospores; they produce unique enzymes on the cell surface that protect them from cold, heat, and desiccation.

Many types of prokaryotes are motile

Can you imagine trying to swim through molasses? Water has the same relative viscosity to prokaryotes that molasses has to humans. Most motile prokaryotes manage to move by means of rotating **flagella**. The number and location of flagella are important in classifying some bacterial species.

Unlike eukaryotic flagella, prokaryotic flagella do not consist of microtubules (see Chapter 4). A bacterial flagellum is a long, thin appendage consisting of three parts: a basal body, a hook, and a single filament (FIG. 25-5). The basal body is a complex structure that anchors the flagellum into the cell wall by disc-shaped plates. The curved hook connects the basal body to the long, hollow filament that extends into the outside environment.

The basal body is a motor, somewhat like the propeller of a boat motor. The bacterium uses energy from ATP to pump protons out of the cell. Diffusion of these protons back into the cell powers the motor that spins the flagellum. The rotary motion generated pushes the cell much like a propeller pushes a boat through the water. The flagellum rotates counterclockwise, pushing the cell forward.

Archaea have a rotating appendage for motility called an *archaellum* (formerly referred to as an archaeal flagellum). The archaellum is thinner than a bacterial flagellum. In fact, it is more similar to a type of bacterial pili than to bacterial flagella. Biologists have determined that the structure of the motor and the assembly of the flagellum in archaea evolved differently from those of bacteria.

Prokaryotic flagella and archaella perform other functions in addition to swimming. Some prokaryotes use their

(a) Color-enhanced TEM of *Vibrio cholerae*. This flagellate bacterium causes cholera in humans.

(b) Structure of a bacterial flagellum. The basal body is the motor. It consists of a series of disc-shaped plates that anchor the flagellum to the cell wall and plasma membrane. These plates spin the hook and filament of the flagellum.

Figure 25-5 The bacterial flagellum

flagella or archaella to swarm, to adhere to surfaces, and to participate in *biofilm* formation (a biofilm is a community of microorganisms attached to a surface). Researchers have documented that bacteria use flagella to sense wetness. A recent study reported that some archaea can interact with one another by their archaella, resulting in the formation of a biofilm composed of more than one species. Prokaryotes that lack flagella or archaella may move by gliding or twitching.

Cannulae and *hami* are extracellular structures that are unique to archaea. Cannulae are hollow glycoprotein tubes that extend from cells forming a network. Cannulae are extremely resistant to heat. They are produced by *Pyrodictium*, a genus of archaea that live in marine hydrothermal habitats. Hami are complex archaeal cell appendages that have been discovered entwined with bacterial filaments in sulfurous springs. Hami are helical, have barbs along the length of the filament, and have a three-part hook at the distal end, which facilitates attachment to surfaces. Cannulae and hami are adaptations to the extreme environments that many archaea inhabit.

Prokaryotes that propel themselves do not move aimlessly. Many prokaryotes exhibit *chemotaxis*, movement in response to chemicals in the environment. For example, prokaryotes move toward food and may also move toward one another using diverse signaling mechanisms. Some bacteria and archaea move away from certain harmful chemicals. In addition, many prokaryotes exhibit *phototaxis*, movement in response to light in the environment.

CHECKPOINT 25.1

- **CONNECT** How do bacteria and archaea differ from each other? Contrast prokaryotic cells with eukaryotic cells.
- **CONNECT** How do gram-positive and gram-negative bacteria differ? Why is this difference important to humans?
- **CONNECT** Contrast a bacterial flagellum with a eukaryotic flagellum.

25.2 Prokaryote Reproduction and Evolution

LEARNING OBJECTIVES

- 4 Describe asexual reproduction in prokaryotes and summarize three mechanisms (transformation, transduction, and conjugation) that may lead to genetic recombination.
- 5 State specific factors that contribute to the rapid evolution of bacteria and archaea.

The genetic material of a prokaryote is located in the nuclear area but is not surrounded by a nuclear envelope. In most species the genetic material consists of a single, circular DNA molecule. If stretched out to its full length, this molecule would be about 1000 times as long as the cell itself. Unlike the DNA in eukaryotic chromosomes, prokaryote DNA has little protein associated with it.

In addition to their genomic DNA, most bacteria and archaea have one or more **plasmids**, smaller circular fragments of DNA. Bacterial plasmids often have genes that code for catabolic enzymes, for genetic exchange, or for resistance to antibiotics. Bacterial plasmids replicate independently of the genomic DNA or become integrated into it (see Chapter 15). Replication mechanisms for archaeal plasmids have not yet been discovered.

Rapid reproduction contributes to prokaryote success

Prokaryotes are extremely successful organisms in terms of their numbers and distribution. Their success is in large part due to their remarkable ability to reproduce rapidly. Prokaryotes reproduce asexually, generally by **binary fission**, a process in which one cell divides into two similar cells (see Fig. 10-12). First the circular DNA replicates, and then an ingrowth of both the plasma membrane and the cell wall forms a transverse wall.

Binary fission occurs with remarkable speed. Under ideal conditions, some bacterial species divide in less than 20 minutes. At this rate, if nothing interfered, one bacterium could give rise to more than one billion bacteria within 10 hours! Prokaryotes cannot reproduce at this rate for very long, however, before lack of food or the accumulation of waste products slows their population expansion.

Bacteria and archaea also commonly reproduce by **budding**. In budding a cell develops a bulge, or bud, that enlarges, matures, and eventually separates from the mother cell. Some prokaryotes divide by **fragmentation**. In this process, walls develop within the cell, which then separates into several new cells.

Prokaryotes transfer genetic information

Although sexual reproduction involving the fusion of gametes does not occur in prokaryotes, genetic material can be exchanged among bacteria and among archaea and also between domains. Such exchange of genes, called *gene transfer*, results in genetic recombination. Transfer of genetic material from parent to offspring is called **vertical gene transfer**. **Horizontal gene transfer** occurs when an organism (or virus) transfers genetic material to another organism that is not its offspring. Gene transfer among prokaryotes takes place by three different mechanisms: transformation, transduction, and conjugation.

1. When prokaryotes die, they release DNA that can be taken in by certain other prokaryotes. In **transformation** a prokaryotic cell takes up fragments of foreign DNA (or RNA) released by another prokaryotic cell. The foreign DNA must bind to DNA-binding proteins on the surface of the host cell. Once it enters the host cell, segments of the foreign DNA may be exchanged with homologous segments of the host DNA (reciprocal recombination) (FIG. 25-6). Recall from Chapter 12 that Oswald T. Avery and his colleagues identified DNA as the agent that transformed bacterial cells and showed that DNA is the chemical basis of heredity.

Foreign DNA can also be taken up as plasmids. When that occurs, DNA does not undergo recombination; instead, it remains as a plasmid separate from the prokaryotic chromosome.

Figure 25-6 Transformation

In transformation a prokaryote takes in foreign DNA from its environment. The host cell exchanges some of its own DNA with homologous segments of the foreign DNA, resulting in a recombinant cell.

2. In a different process of horizontal gene transfer, **transduction**, a phage carries bacterial or archaeal genes from one bacterial or archaeal cell into another (FIG. 25-7). Normally, a phage contains only its own DNA. However, sometimes a phage incorporates some of the DNA of its host. Then, when the phage infects another bacterium or archaeon, it transfers that DNA to its new host. The chromosome of this new host then becomes a recombination of its own original DNA and DNA from another bacterium or archaeon.
3. In **conjugation**, two cells of different mating types come together, and genetic material is transferred from one to the other (FIG. 25-8). In contrast to transformation and transduction, conjugation involves contact between two cells.

Conjugation has been most extensively studied in the bacterium *Escherichia coli*. In the *E. coli* population, there are *donor cells*, or *F⁺ cells*, which have DNA that can be transmitted to *recipient cells*, or *F⁻ cells*. *F⁺ cells* have a DNA sequence known as the *F factor* (*F* stands for fertility) that is necessary for a bacterium to serve as a donor during conjugation. The *F* factor can be in the form of a plasmid, or it can be part of the DNA in the bacterial chromosome.

F genes encode enzymes essential for transferring DNA. Certain *F* genes encode **sex pili**, long, hair-like extensions that project from the cell surface. The sex pilus of an *F⁺* cell recognizes and binds to the surface of an *F⁻* cell, forming a cytoplasmic conjugation bridge between the two cells. The *F* plasmid replicates itself, and DNA is transferred from donor to recipient bacterium through the conjugation bridge. *F* plasmids may also have other types of genes, including those that determine resistance to antibiotics.

Figure 25-7 Transduction

In transduction a phage transfers bacterial DNA from one bacterium to another, resulting in genetic recombination. Transduction is an important means of horizontal gene transfer.

Evolution proceeds rapidly in prokaryote populations

Because prokaryotes reproduce rapidly by binary fission, mutations are quickly passed on to new generations. Mutations that confer some advantage spread through the population, and the effects of natural selection are quickly evident.

Horizontal gene transfer greatly contributes to the rapid evolution that takes place in prokaryotes. Acquisition of new DNA and genetic recombination are important sources of the

During conjugation, horizontal gene transfer takes place, resulting in genetic recombination.

(a) **Color-enhanced SEM of *E. coli* bacteria conjugating.** The bacteria are connected by a sex pilus. When stimulated by the contact, the cells pull close together and form a conjugation bridge between donor and recipient cells (shown in b).

Figure 25-8 Conjugation

In conjugation, a donor bacterium transfers plasmid DNA to a recipient bacterium. Conjugation requires cell-to-cell contact.

CONNECT Why might it be advantageous for a bacterial cell to receive the F plasmid from another cell?

genetic variation required for diversification and adaptation. New DNA introduced into a prokaryote's genome represents raw material for evolution. New genes are subject to mutation and are acted on by the forces of natural selection. The changes in the genetic material are passed to succeeding generations by binary fission. Changes that result in adaptation can quickly spread through future bacterial and archaeal populations.

CHECKPOINT 25.2

- How do prokaryotes reproduce? What mechanisms result in gene transfer?
- **CONNECT** How does transduction contribute to the rapid evolution of bacterial populations?
- **VISUALIZE** Draw the steps that take place during conjugation.

25.3 Nutritional and Metabolic Adaptations

LEARNING OBJECTIVE

- 6 Describe the principal modes by which prokaryotes carry on nutrition and energy capture, and compare their requirements for oxygen.

Some prokaryotes are *autotrophs* (*-troph* comes from a Greek word that means “nutrition”), and others are *heterotrophs*. **Autotrophs** are able to use inorganic compounds, such as carbon dioxide, as a source of carbon for manufacturing their organic molecules. Most prokaryotes are **heterotrophs** that obtain carbon atoms from the organic compounds of other organisms.

Based on *two principal ways of capturing energy*, an autotroph is classified as a chemotroph or a phototroph. **Chemotrophs** obtain their energy from chemical compounds. **Phototrophs** capture energy from light. As early as 3.5 billion years ago,

the ability to use the sun as an energy source evolved in early prokaryotes. These early phototrophs used hydrogen sulfide to reduce carbon dioxide. They released sulfur as a waste product. About 2.7 billion years ago, the ability to use water rather than hydrogen sulfide to reduce carbon dioxide evolved in early cyanobacteria, and oxygen was released as a waste product. When we consider the source of carbon *and* the source of energy, we can classify prokaryotes into four main groups (TABLE 25-1):

1. **Photoautotrophs**, such as cyanobacteria, use the energy from sunlight to synthesize organic compounds from carbon dioxide and other inorganic compounds.
2. The majority of archaea and some bacteria are **chemoautotrophs**, which use carbon dioxide as a carbon source, but do not use sunlight as their energy source. Instead, they obtain energy by oxidizing inorganic chemical substances such as ammonia (NH_3) or hydrogen sulfide (H_2S).
3. **Photoheterotrophs**, such as the purple nonsulfur bacteria, obtain their carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight.
4. The majority of bacteria are **chemoheterotrophs**. They depend on organic molecules for both their carbon and energy. Many prokaryote chemoheterotrophs are free-living **decomposers** that obtain their carbon and energy from dead organic matter. These organisms are sometimes called *saprotrophs*. Some bacterial chemoheterotrophs are pathogens, which obtain their nourishment from the organisms they infect. They harm their hosts by causing diseases. Other heterotrophic bacteria benefit their hosts. For example, some of the bacteria that inhabit the human large intestine produce vitamin K and certain B vitamins that benefit their hosts.

Most prokaryotes require oxygen

Whether they are heterotrophs or autotrophs, most bacterial cells and many archaeal cells are **aerobic** and require oxygen for cellular respiration. Many are **facultative anaerobes** that use oxygen for cellular respiration if it is available but can carry on metabolism anaerobically when necessary. Other prokaryotes are **obligate anaerobes** that carry on anaerobic respiration; they respire with terminal electron acceptors other than oxygen, such as sulfate (SO_4^{2-}), nitrate (NO_3^-), or iron (Fe^{2+}). Some obligate anaerobes, including certain archaea, are actually killed by even low concentrations of oxygen.

Some prokaryotes fix and metabolize nitrogen

All organisms require nitrogen to manufacture amino acids and nucleic acids. Some bacteria (e.g., certain cyanobacteria) and archaea (e.g., methanogens) can reduce nitrogen in the atmosphere to ammonia. This process is called **nitrogen fixation**. Ammonia produced by nitrogen fixation is converted to ammonium ions (NH_4^+). Nitrogen-fixing prokaryotes can use these simple forms of nitrogen to produce organic compounds.

Certain prokaryotes convert ammonia or ammonium ions to nitrite (NO_2^-), and others convert nitrite to nitrate (NO_3^-). This process, called **nitrification**, converts nitrogen to a form that can be used by plants and fungi. Animals obtain nitrogen from organic compounds when they eat other organisms. As we will discuss in a later section, all other organisms ultimately depend on nitrogen fixation and nitrification by prokaryotes for their survival (discussed further in Chapter 55).

CHECKPOINT 25.3

- How do chemoheterotrophs obtain energy?
- **CONNECT** How do facultative anaerobes differ from obligate anaerobes? How do they differ from aerobes?
- How do prokaryotes obtain nitrogen needed to produce amino acids and nucleic acids?

25.4 The Phylogeny of the Two Prokaryote Domains

LEARNING OBJECTIVES

- 7 Compare characteristics of the three domains: Archaea, Bacteria, and Eukarya.
- 8 Distinguish between the main groups of archaea and identify specific types of archaea belonging to each group.
- 9 Describe the main groups of bacteria discussed in this chapter.

Under a microscope, most prokaryotes appear rather similar in size and form. However, using sequence analysis of small subunit 16S ribosomal RNA (SSU rRNA), Carl Woese and his co-workers demonstrated that there are two fundamentally different

Table 25-1 Modes of Nutrition and Energy Capture

Mode of Nutrition	Energy Source	Carbon Source	Examples of Organisms
AUTOTROPH			
Photoautotroph	Sunlight	CO_2	Cyanobacteria; purple sulfur bacteria
Chemoautotroph	Inorganic chemicals (e.g., NH_3 , H_2S , Fe^{2+})	CO_2	Certain proteobacteria; most archaea (e.g., methanogens, extreme halophiles)
HETEROTROPH			
Photoheterotroph	Sunlight	Organic compounds	Purple and green nonsulfur bacteria
Chemoheterotroph	Organic compounds	Organic compounds	Free-living decomposers; most bacterial pathogens

groups of prokaryotes (see Chapter 23). Each group has regions of SSU rRNA that have unique nucleotide sequences. These differences are present because after they diverged, prokaryote populations diversified, and mutations occurred that affect RNA sequences. Using such analyses, Woese hypothesized that ancient prokaryotes split into two lineages early in the history of life.

Based on Woese's work and on other recent data, systematists now classify the modern descendants of these two ancient lines in two domains: **Archaea** and **Bacteria** (FIG. 25-9). These groups are thought to have diverged from a common ancestor about 4 billion years ago. Archaea and bacteria were the only living organisms on our planet for about 2 billion years. Thus, archaea and bacteria have had a very long time to evolve and adapt to all types of environments. Their diversity is staggering. Horizontal gene transfer has contributed to the diversity of these organisms. As a result of gene transfer, sometimes from distantly related species, the genomes of archaea and bacteria are actually a mix of genes from many prokaryotes.

Key characters distinguish the three domains

Several key characters distinguish archaea from bacteria. In contrast to bacteria, archaea do not have peptidoglycan in their cell walls. Although their plasma membranes are structurally similar, they are chemically unique. In the plasma membranes of bacteria and eukaryotes, straight-chain fatty acids are linked to glycerol molecules by *ester linkages*. In contrast, fatty acid components are not found in archaea. Instead, branched-chain hydrocarbons (synthesized from isoprene units) are bonded to glycerol by *ether linkages* (TABLE 25-2).

The absence of a second electronegative oxygen atom makes ether linkages stronger than ester linkages. This unique membrane structure may contribute to the ability of archaea to survive and thrive in harsh environments.

In some ways, archaea are more like eukaryotes than like bacteria. For example, archaea do not have the simple RNA polymerase found in bacteria. Like eukaryotes, their translation process begins with methionine, whereas in bacteria, translation begins

Figure 25-9 Three domains

This highly simplified diagram depicts some representative taxa of domain Bacteria and domain Archaea. The relationships illustrated are based on molecular data. As taxonomists consider additional data, these relationships will likely be modified.

with formylmethionine (see Chapter 13). In addition, several antibiotics that affect bacteria do not affect archaea or eukaryotes.

Bacteria also share some characteristics (that are absent in archaea) with eukaryotes. For example, as stated above, bacteria and eukarya both have ester-linked membrane lipids, whereas archaea have ether-linked membrane lipids. Some microbiologists hypothesize that eukaryotes are a product of fusion between an archaeon, which contributed components for transcription and translation, and a bacterial symbiont, which contributed enzymes necessary for energy metabolism.

Using molecular data analyses, researchers further hypothesize that eukaryotes arose from an archaeal ancestor. That ancestor may have been a member of a recently discovered clade of archaea, **Lokiarchaeota**. Because members of this clade have several eukaryotic characteristics, some systematists propose that the eukaryotes branched from the Lokiarchaeotes. If accurate, this hypothesis would make the eukaryotes part of domain Archaea, eliminating the domain Eukarya!

Taxonomy of archaea and bacteria continuously changes

Prokaryote taxonomy is based largely on molecular data, mainly RNA sequencing and more recently on sequencing entire genomes. Groups that branched off earlier had more time to accumulate mutations in their SSU rRNA. Their nucleotide sequences are less similar than those of groups that

Table 25-2 Comparison of the Three Domains

Characteristic	Bacteria	Archaea	Eukarya
Nuclear envelope	Absent	Absent	Present
Membrane-enclosed organelles	Absent	Absent	Present
Circular chromosome	Present (linear in some species)	Present	Absent
Number of chromosomes	Typically one (may also have plasmids)	Typically one (may also have plasmids)	Typically many
Histones associated with DNA	Absent	Present	Present
Peptidoglycan in cell wall	Present	Absent	Absent
Structure of lipids in plasma membrane	Straight-chain fatty acids bonded to glycerol by ester linkages	Branched-chain hydrocarbons linked to glycerol by ether linkages	Straight-chain fatty acids bonded to glycerol by ester linkages
Size of ribosomes	70S ¹	70S	80S except in mitochondria and chloroplasts
RNA polymerase	One relatively simple RNA polymerase	One relatively complex RNA polymerase	Several relatively complex RNA polymerases
Translation	Begins with formylmethionine	Begins with methionine	Begins with methionine
Growth above 70°C	Yes	Yes	No

¹ The numbers 70S and 80S refer to the sedimentation coefficient (a measure of relative size) when centrifuged.

diverged more recently. Microbiologists who are developing phylogenetic trees based on sequencing entire genomes argue that there may be 1000 genes that code proteins for every 1 gene that codes an rRNA. These researchers prefer to consider the proportions of genes (or proteins) that genomes of various groups have in common. Taxonomy of archaea and bacteria continuously changes as systematists study new molecular data that provide new clues to the phylogeny of these groups.

Although prokaryotic taxonomy is controversial and continuously changing, about 14,000 species of prokaryotes have been classified. Hundreds of thousands of additional species are thought to exist. The editors of *Bergey's Manual of Systematic Bacteriology*, considered the definitive reference text by microbiologists, have divided archaea into 4 groups (phyla) and bacteria into more than 30 groups (phyla) based on 16S rRNA analyses. Systematists, however, have proposed additional groups (phyla) of archaea based on the numerous and continuing discoveries of previously unidentified organisms.

Most archaea live in marine and soil habitats, and many thrive in harsh environments

Domain Archaea consists of several widely recognized groups (phyla, clades), including *Crenarchaeota*, *Euryarchaeota*, *Nanoarchaeota*, and *Korarchaeota*. This phylogeny is based on 16S rRNA and on sequencing of entire genomes. Based on continued detection of previously unidentified archaea and sequencing of archaeal genomes, systematists estimate that more than a dozen additional groups may be added.

The **Crenarchaeota** include **extreme thermophiles**, archaea that require a very high temperature or very low temperature for growth. The optimum temperature for many is greater than 80°C (176°F) and some thrive at temperatures greater than 100°C. Some crenarchaeotes have the highest growth temperatures known of any organisms. Some species inhabit acidic environments. One species is found in the hot

sulfur springs of Yellowstone National Park at temperatures near 80°C and pH values of 1 to 2, the pH of concentrated sulfuric acid (**FIG. 25-10a**). Other crenarchaeotes inhabit volcanic areas under the sea. One species, found near deep-sea hydrothermal vents on the seafloor of the Pacific Ocean, lives at temperatures ranging from 80°C to 120°C. In contrast, some Crenarchaeota species live in very cold environments (1.8°C).

Studies have identified many diverse species of Crenarchaeota in soil and fresh water, demonstrating that members of this clade are common to most environments. Crenarchaeotes are a main contributor to carbon fixation. They are also an important part of the plankton in cold, oxygen-rich seas. A few are photoheterotrophs.

The **Euryarchaeota** also include many archaea that inhabit extreme environments. This group includes methanogens, extreme aerobic and anaerobic thermophiles, acidophiles, and halophiles (some extreme) (**FIG. 25-10b**). The **methanogens** (methane producers) are a large, diverse group that inhabit oxygen-free environments in sewage, swamps, and the digestive tracts of humans and other animals. They are obligate anaerobes that produce methane gas from simple carbon compounds. The methanogens are important in recycling components of organic products of organisms that inhabit swamps. Methanogens that inhabit the digestive tracts of cows and other grazing animals produce methane, which is belched out by the animals. Methanogens produce more than 80% of the methane (more than 2 billion tons each year) in Earth's atmosphere. Methanogens are also found in marine sediments (**FIG. 25-10c**). Methane is an important greenhouse gas (discussed in Chapter 57).

Extreme halophiles are heterotrophs that require large amounts of Na⁺ for their growth. They live in saturated brine solutions such as salt ponds, the Dead Sea, and Great Salt Lake. The extreme halophiles use aerobic respiration to make ATP. However, they also carry out a form of the Calvin cycle (a part of photosynthesis) in which they capture the energy of sunlight using a purple pigment (*bacteriorhodopsin*). This pigment is very similar to the pigment rhodopsin involved in animal vision.

(a) **Extreme thermophiles.** Orange, yellow, and green colonies of extreme thermophiles thrive in the Grand Prismatic Spring in Yellowstone National Park in Wyoming. Thermophilic red algae contribute the green color.

(b) **Extreme halophiles.** These seawater salt-evaporation ponds are colored from the large number of extreme halophiles that inhabit them. The colors come from pigments in the cell membranes. These archaea are harmless, and the ponds are used to produce salt commercially.

(c) **SEM of *Pyrococcus furiosus*, an anaerobe that inhabits marine sediments.** This methanogen is highly resistant to heat; its optimum temperature is 100°C. *Pyrococcus* is classified as a euryarchaeote.

Figure 25-10 Archaea that inhabit extreme environments

Korarchaeota is a clade of Archaea that appears to have branched before the Crenarchaeota and Euryarchaeota branches separated. Korarchaeota have some characteristics of Crenarchaeota and some features of Euryarchaeota. Korarchaeotes have been found in terrestrial hot springs.

The first member of the **Nanoarchaeota**, *Nanoarchaeum equitans*, was discovered in a hydrothermal vent in 2002. This marine microbe is a very small (400 nm) anaerobic, extreme thermophile with a very small genome (less than 500,000 nucleotides). It lives attached to another archaeon, an autotroph, and depends on its host for many of its metabolic needs. A few other nanoarchaeotes have been identified in hot springs throughout Yellowstone National Park.

Two supergroups have recently been proposed. Supergroup “TACK” includes four groups (Thaumarchaeota, Aigarchaeota, Crenarchaeota, and Korarchaeota). The “Asgard” clade includes the Lokiarchaeota, discussed previously, along with three other newly discovered archaea groups (Thorarchaeota, Odinararchaeota, and Heimdallarchaeota). Asgard archaea appear to be closely related to TACK archaea.

As more archaea have been discovered and studied, it has become evident that there are more archaea in marine and soil environments than in extreme habitats. The archaea are important in biogeochemical cycles and in marine food chains. Although archaea continue to be discovered on and in humans, no pathogenic archaea have been identified.

Bacteria are the most familiar prokaryotes

Bacteria have been known and studied much longer than the archaea. Bacteria are also widely distributed in the environment. Five major groups are considered here: proteobacteria (gram-negative), cyanobacteria (gram-negative), gram-positive bacteria, chlamydias (gram-negative), and spirochetes (gram-negative). These groups are summarized in **TABLE 25-3**.

CHECKPOINT 25.4

- What types of environments are inhabited by archaea? Why are methanogens important?
- **CONNECT** How does each of the following groups of bacteria (described in Table 25-3) affect the biosphere: alpha proteobacteria, cyanobacteria, and chlamydias?

25.5 Impact on Ecology, Technology, and Commerce

LEARNING OBJECTIVES

- 10 Identify the critical ecological roles played by prokaryotes and briefly describe their relationships with other organisms.
- 11 Describe some of the important roles played by prokaryotes in commerce and technology.

Prokaryotes inhabit virtually every environment on Earth and are vital members of the biosphere. They affect other organisms directly and by the ecological roles they play. Prokaryotes produce nitrogen in forms usable by other organisms, and they are a reservoir for nutrients. These microscopic organisms recycle nutrients and are key players in biogeochemical cycles.

Prokaryotes form intimate relationships with other organisms

Some prokaryote species have coevolved with eukaryotes and are interdependent with them. All plants and animals harbor a community of microorganisms referred to as **microbiota**. (This term has replaced *microflora*, which is a misnomer because “flora” refers to plants.) An estimated 37 to more than 100 trillion symbiotic bacteria, archaea, and (a few) eukaryotic microorganisms normally inhabit the human body! This number is equal to or up to triple the number of the body’s own cells (more than 37 trillion).

Normal microbial populations have been shown to have multiple effects, including preventing harmful microorganisms from flourishing. The term **microbiome** refers to the community of these microorganisms, including their genomes and all of their interactions. Rapid DNA sequencing has greatly facilitated microbiome research because there are thousands of species of these organisms and many are difficult to grow in culture. Through the *Human Microbiome Project* supported by the National Institutes of Health, investigators have mapped the human **microbiome**, creating a database of more than 10,000 microorganisms. Through continued research, we are developing an ever-increasing understanding of the critical control and effects these symbionts have on human health and disease.

Prokaryotes interact with other organisms in both beneficial and harmful ways. An intimate relationship between members of two or more species is called **symbiosis**. The partners in a symbiotic relationship are called **symbionts**. Symbiotic relationships arise by coevolution. Three forms of symbiosis are mutualism, commensalism, and parasitism.

Mutualism is a symbiotic relationship in which both partners benefit. Cows and other ruminants (cud-chewing animals) have mutualistic relationships with bacteria and archaea that inhabit their digestive tracts. Ruminants lack enzymes for digesting cellulose. They provide the prokaryotes with a nutrient-rich home, and the prokaryotes digest the cellulose for them.

Trillions of bacteria and some archaea inhabit the nutrient-rich human intestine. Some of them are mutualistic bacteria. For example, in exchange for nutrients and a place to live, *Bacteroides* break down indigestible complex carbohydrates into sugars that their human host can absorb. These bacteria also produce certain vitamins that their host absorbs and uses. In addition, *Bacteroides* promote proliferation of blood vessels that improve intestinal function. Investigators have reported that these bacteria can turn on specific genes in cells of the host’s intestine, inducing synthesis of a compound that kills competing bacteria.

In **commensalism**, one partner benefits, and the other is neither harmed nor helped. Many prokaryotes that inhabit the human intestine are commensals that live on unused food. In **parasitism**, one partner lives on or in the other. The **parasite** benefits, and the **host** is harmed. Disease-causing bacteria are usually not considered obligate parasites because these *pathogens* typically can survive in other ways.

Some types of bacteria may influence evolution of other species The proteobacteria *Wolbachia* infect many invertebrates, including insects, spiders, crustaceans, and nematodes

(roundworms). *Wolbachia* are transmitted from generation to generation in the eggs of their hosts, so male hosts are not useful to them. Consequently, these parasites limit or eradicate males from the population. In some insect species, infected males can reproduce only when they mate with infected females carrying the same *Wolbachia* strain. In some other species, these parasites convert male insects into females. In some wasp species, *Wolbachia* induces **parthenogenesis**, the development of unfertilized eggs into adult organisms. Because they affect reproduction in their hosts, *Wolbachia* and other reproductive parasites may influence evolutionary divergence and even extinction in some species. *Wolbachia* may also affect evolution by horizontal gene transfer.

Many prokaryotes form biofilms Many types of bacteria and archaea that inhabit watery environments form **biofilms**, dense communities of microorganisms that attach to solid surfaces. The prokaryotes secrete a slimy, glue-like substance rich in polysaccharides and become embedded in this matrix. A biofilm may consist of layers up to 200 μm thick. Biofilms are communities of many microorganisms and may consist of many species of bacteria, archaea, fungi, and protists. Scientists have found evidence of ancient biofilms in sediments from coastal marine environments 3.5 billion years old.

The dental plaque that forms on teeth is a familiar example of a biofilm (FIG. 25-11 on page 532). Dental plaque consists of several hundred different types of bacteria and archaea. Biofilms also commonly form on the surfaces of contact lenses and catheters. They sometimes develop on surgical implants such as pacemakers and joint replacements. Biofilms, which form on and inside plants, cause considerable crop loss.

Prokaryotes play key ecological roles

Bacteria, especially actinomycetes and myxobacteria, are the most numerous inhabitants of soil. As described earlier in this chapter, many prokaryotes are essential decomposers, chemoheterotrophs that break down dead organic matter and wastes. They use the products of decomposition as an energy source. When prokaryotes break down organic compounds, many of their components, including nitrogen, oxygen, carbon, phosphorus, sulfur, and certain trace elements, are recycled. (The roles of bacteria and archaea in biogeochemical cycles, particularly the nitrogen cycle, are discussed in Chapter 55.)

Nitrogen is constantly removed from the soil by plants and other natural processes as well as by human activities such as agriculture. Plant growth depends on the availability of usable nitrogen, so it must be continually added to the soil. Several types of bacteria, including cyanobacteria, and some archaea transform atmospheric nitrogen to forms that can be used by plants (see Table 25-3). Marine archaea that carry out nitrification are important in the ocean nitrogen cycle.

Rhizobial prokaryotes, motile inhabitants of the soil, form mutualistic relationships with the roots of legumes, a large family of plants that includes important crops such as beans, peas, and peanuts. The infected plant cells form tumorlike nodules in which the microbes reside and fix nitrogen (see Fig. 55-9). The prokaryotes supply the plant with the nitrogen it requires, and

Proteobacteria (Gram-Negative)

Rhizobia (*Rhizobium leguminosarum*) in root nodule
Rhizobia are nitrogen-fixing bacteria.

SEM of bacteria (*Neisseria gonorrhoeae*) that cause gonorrhea
In this colorized SEM, these beta proteobacteria (blue) are infecting a human epithelial cell (purple).

SEM of *Escherichia coli* colony
E. coli are gamma proteobacteria.

SEM of fruiting body of the myxobacterium *Stigmatella aurantiaca*
Protective resting cells within the fruiting bodies are very resistant to heat and drying. Myxobacteria are delta proteobacteria.

SEM of *Helicobacter pylori* attached to the epithelial lining of the stomach

A large, very diverse clade of gram-negative bacteria. Based on rRNA sequences, the group is divided into five subgroups designated as alpha, beta, gamma, delta, and epsilon.

ALPHA PROTEOBACTERIA

Includes many symbionts of plants and animals, and some pathogens. *Rhizobium* species live symbiotically in root nodules of legumes (e.g., beans) and convert atmospheric nitrogen to a form usable by plants (nitrogen fixation). **Rickettsias** are very small, rod-shaped bacteria. A few species are pathogenic to humans and other animals; transmitted by arthropods through bites or through contact with their excretions. Rickettsias cause typhus (transmitted by fleas and lice) and Rocky Mountain spotted fever (transmitted by ticks). Members of the SAR11 clade are extremely abundant in the ocean.

BETA PROTEOBACTERIA

Several diverse groups, including *Nitrosomonas*, which oxidizes ammonia. Pathogenic bacteria in this group include *Neisseria gonorrhoeae*, which causes gonorrhea.

GAMMA PROTEOBACTERIA

Includes the **enterobacteria**, decomposers that live on decaying plant matter, pathogens, and a variety of bacteria that inhabit humans. Although *Escherichia coli* is a normal inhabitant of the animal intestinal tract, certain strains can cause moderate to severe diarrhea. One species of *Salmonella* infects food and produces a toxin that causes a form of food poisoning; another species causes typhoid fever.

Vibrios are mainly marine; some are bioluminescent. *Vibrio cholerae* causes cholera.

Pseudomonads are heterotrophs that produce nonphotosynthetic pigments; cause disease in plants and animals, including humans.

Purple sulfur bacteria are photoautotrophs that do not produce oxygen.

DELTA PROTEOBACTERIA

Includes the **myxobacteria** (slime bacteria), which secrete slime and glide or creep along. When nutrients are exhausted, these bacteria aggregate into stalked, multicellular reproductive structures called fruiting bodies. Bacterial cells within the fruiting body enter a resting stage. When conditions are favorable, resting cells become active.

EPSILON PROTEOBACTERIA

A small group of bacteria that inhabit the animal digestive tract. *Helicobacter* can cause peptic ulcers.

Continued

Table 25-3 Major Groups of Bacteria (continued)

Gram-Positive Bacteria

SEM of *Actinomycetes mashaensis* (color-enhanced)

These soil-dwelling bacteria form filamentous colonies.

SEM of *Mycoplasma* on fibroblast cells

Actinomycetes superficially resemble fungi. However, they have peptidoglycan in their cell walls, lack nuclear envelopes, and have other prokaryotic characteristics. Most actinomycetes are saprotrophs that decompose organic materials in soil. Some are anaerobic. Some actinomycetes cause serious lung disease and other infections in humans and other animals.

Several species of the genus ***Streptomyces*** produce antibiotics such as streptomycin, erythromycin, chloramphenicol, and the tetracyclines. *A. mashaensis* produces streptomycin, as well as an antifungal antibiotic.

Lactic acid bacteria ferment sugar, producing lactic acid as the main end product. Inhabit decomposing plant material, milk, and other dairy products; responsible for the characteristic taste of yogurt, pickles, sauerkraut, and green olives. Among the normal inhabitants of the human mouth and vagina.

Mycobacteria are slender, irregular rods; contain a waxy substance in their cell walls. One species causes tuberculosis; another causes leprosy.

Streptococci inhabit the mouth and digestive tract of humans and some other animals. Among the harmful species are those that cause “strep throat,” dental caries, a form of pneumonia, scarlet fever, and rheumatic fever.

Staphylococci normally live in the nose and on skin. Opportunistic pathogens that cause disease when the immunity of the host is lowered. *Staphylococcus aureus* causes boils and skin infections (some extremely serious); may infect wounds. Certain strains of *S. aureus* cause a form of food poisoning; other strains cause toxic shock syndrome (see Fig. 25-14).

Clostridia are anaerobic. One species causes tetanus; another causes gas gangrene. *Clostridium botulinum* can cause botulism, an often fatal type of food poisoning.

The **mycoplasmas** are a group of very small bacteria that lack cell walls. They may have evolved from bacteria with gram-positive cell walls. They inhabit soil and sewage; some are parasitic on plants or animals. Some inhabit human mucous membranes but do not generally cause disease; one species causes a mild type of bacterial pneumonia in humans.

Cyanobacteria (Gram-Negative)

LM of *Anabaena*, a filamentous cyanobacterium that fixes nitrogen

Nitrogen fixation takes place in the rounded cells, called *heterocysts*.

Cyanobacteria contain chlorophyll *a* and are the only prokaryotes that, like plants and algae, carry on photosynthesis that generates oxygen. Cyanobacteria were the first organisms that carried on oxygen-generating photosynthesis; very important in the evolution of life-forms because their photosynthesis changed the early reducing atmosphere on Earth to an oxidizing atmosphere. Chloroplasts are thought to have evolved from endosymbiotic cyanobacteria. Inhabit ponds, lakes, swimming pools, moist soil, dead logs, and tree bark. Some form filaments; other species are solitary. As primary producers, they are an important source of food for marine and freshwater organisms. Some species have special structures that fix nitrogen.

Chlamydias (Gram-Negative)

TEM of *Chlamydia trachomatis* in human oviduct cell

Chlamydias lack peptidoglycan in their cell walls. They are energy parasites, completely dependent on their hosts for ATP. Infect almost every species of bird and mammal. A strain of *Chlamydia* causes trachoma, the leading cause of blindness in the world. Sexually transmitted chlamydias are the major cause of pelvic inflammatory disease in women.

Spirochetes (Gram-Negative)

LM of *Treponema pallidum*, the spirochete that causes syphilis

Spirochetes are spiral-shaped bacteria with flexible cell walls; move by means of unique internal flagella called *axial filaments*. Some species are free-living, whereas others form symbiotic associations; a few are parasitic. *Treponema pallidum* causes syphilis.

Figure 25-11 A familiar biofilm: dental plaque

Colorized SEM of dental plaque, which consists of a film of bacteria (red) embedded in a matrix of glycoprotein (blue). Bacteria in the plaque can produce acids that erode tooth enamel, leading to tooth decay.

the plant provides the prokaryotes with organic compounds, including sugar needed for cellular respiration. Because many soils are deficient in nitrogen, legumes that have formed mutualistic associations with rhizobial microbes have a decided advantage over other plants. When the legumes die and are decomposed, the fixed nitrogen is released and enriches the soil.

Cyanobacteria are the only prokaryotes that carry on photosynthesis using water as the electron source and generating oxygen. During this process they fix huge amounts of carbon dioxide into organic molecules.

Microbiologists are only beginning to unravel the mysteries of prokaryote ecology. For example, alpha proteobacteria in the SAR11 clade are among the most successful organisms on Earth. Although they are one of the most abundant organisms in the Atlantic Ocean, they were not successfully cultured until 2002, and very little is known about their ecological role. There is evidence that they are important in cycling carbon, nitrogen, and sulfur in the ocean.

Prokaryotes are important in many commercial processes and in technology

Some microorganisms produce *antibiotics*. These compounds limit competition for nutrients by inhibiting or destroying other microorganisms. By the 1950s, antibiotics had become important clinical tools that transformed the treatment of infectious disease. Today, more than 100 clinically useful antibiotics are available, and literally tons of antibiotics are produced annually. Pharmaceutical companies obtain most antibiotics from three groups of microorganisms: a large group of gram-positive soil bacteria, the *actinomycetes*; gram-positive bacteria of the genus *Bacillus*; and molds (eukaryotes belonging to kingdom

Fungi). Researchers have discovered that some archaea also produce antimicrobial substances, called **archaeocins**, which may someday be used in the production of new antibiotics.

Because of their prolific reproduction rates, bacteria are ideal “factories” for the production of biomolecules. Microbiologists have genetically engineered bacteria to produce certain vaccines, human growth hormone, insulin, and many other clinically important compounds (see Chapter 15). Researchers are developing genetically engineered bacteria for production of many other medically and agriculturally useful products.

Microbial fermentation helps produce many foods and beverages. Lactic acid bacteria are used in producing acidophilus milk, yogurt, pickles, olives, and sauerkraut. Several types of bacteria are used in the production of cheese. Bacteria are involved in making fermented meats such as salami and in producing vinegar, soy sauce, chocolate, and certain B vitamins (B_{12} and riboflavin).

Bacteria are used in **bioremediation**, the process of using microorganisms (and sometimes other organisms) to detoxify or remove oil, gasoline, and other pollutants or toxic chemicals from the environment. Microorganisms break down certain toxins, leaving behind harmless metabolic byproducts such as carbon dioxide and chlorides (FIG. 25-12). More than 1000 different species of bacteria and fungi have been used to clean up various forms of pollution, and microbiologists are searching for others. For example, bacteria and other microorganisms are used in oil spills to break down oil, oxidizing it to CO_2 . Microorganisms are also used in sewage treatment and to break down solid wastes in landfills.

Archaea are also economically important. Archaea that are adapted to high temperatures or extremely acidic conditions, for example, are a source of enzymes that can be used under these extreme conditions. Archaeal enzymes have been added to laundry and industrial detergents and to organic solvents to increase performance at higher temperatures and pH levels. Methanogens are important in the biogas production industry and in sewage treatment. Another archaeal enzyme has been useful in the food industry to convert cornstarch to dextrins (low molecular weight carbohydrates produced by hydrolysis of starch or glycogen).

Molecular biology and forensic biology have greatly benefited from heat-resistant DNA polymerase, derived from the archaeon *Pyrococcus furiosus* (see Fig. 25-10c). Like heat-resistant Taq polymerase, derived from a bacterium, it is used in the polymerase chain reaction (PCR) discussed in Chapter 15. Acidophilic archaea are promising as resources for extracting metal from ores and remediating toxic mining sites.

CHECKPOINT 25.5

- **CONNECT** In what ways do bacteria form relationships with other organisms?
- Where would you expect to find biofilms? Name organisms you would expect to find in biofilms.
- **CONNECT** Describe how prokaryotes are ecologically important. Give specific examples.
- Describe the process of bioremediation.

Figure 25-12 Bioremediation

As they feed on gasoline and certain other waste products in contaminated soil, certain microorganisms convert hydrocarbons in these pollutants to carbon dioxide and water. Photographed at an oil refinery and chemical plant in the United Kingdom.

Pasteur also developed a rabies vaccine, showing that people can be stimulated to develop immunity to disease.

German physician Robert Koch was the first to clearly demonstrate that bacteria cause infectious disease. In 1876, he showed that *Bacillus anthracis* caused anthrax. Using a microscope, Koch observed the bacteria in the blood and spleens of dead sheep. When he inoculated mice with the infected sheep blood, he was able to identify *B. anthracis* in the blood of the mice. He also cultured *B. anthracis* and showed that when he injected the bacteria into healthy mice they developed anthrax.

Koch proposed a set of guidelines, now known as **Koch's postulates**, that are still used to demonstrate that a specific pathogen causes specific disease symptoms: (1) the pathogen must be present in every individual with the disease, (2) a sample of the microorganism taken from the diseased host can be grown in pure culture, (3) a sample of the pure culture causes the same disease when injected into a healthy host, and (4) the

microorganism can be recovered from the experimentally infected host. Sometimes these guidelines cannot be met, as, for example, when certain microorganisms cannot be grown in pure culture. In those situations, other criteria must be used.

25.6 Bacteria and Disease

LEARNING OBJECTIVES

- 12** Describe the roles played by Louis Pasteur and Robert Koch in understanding infectious disease; list Koch's postulates.
- 13** Identify adaptations that have contributed to pathogen success.

A small percentage of bacterial species are important pathogens of plants and animals. Some of the normal bacterial inhabitants are opportunistic pathogens that cause disease only under certain conditions. For example, when the immune system is compromised, opportunistic bacteria increase in number and cause disease. Some important bacterial diseases and the pathogens that cause them are briefly described in **TABLE 25-4**.

Many scientists have contributed to our understanding of infectious disease

The idea that some unknown agent caused disease was debated long before Leeuwenhoek discovered microorganisms with his microscope in the late 1600s. However, not until much later did scientists develop the tools and methods needed to accurately understand the relationships between bacteria and disease. During the late 19th century, several physicians, microbiologists, and chemists working independently laid the foundations for the science of microbiology. French chemist Louis Pasteur disproved the prevailing views of spontaneous generation by demonstrating that sterilization of a sugar and protein culture prevented bacterial growth.

Many adaptations contribute to pathogen success

Pathogenic microorganisms can enter the body in food, dust, or droplets, or through wounds. Many diseases are transmitted by insect or animal bites. To cause disease, a pathogen must adhere to a specific cell type, multiply, and produce toxic substances. Adherence and multiplication occur only when the pathogen competes successfully with the normal microbiota and counteracts the host's defenses against invasion.

Helicobacter pylori, the most common cause of peptic ulcers (ulcers of the stomach and duodenum), is an extremely successful pathogen (**FIG. 25-13**). It is also associated with chronic gastritis (stomach inflammation) and with stomach cancer, the second most common type of cancer in the world. *Helicobacter pylori* inhabits the gastrointestinal tracts of an estimated 40% of adults in developed countries and 80% of adults in developing countries. Among its many adaptations is its ability to produce an alkaline shield around itself that protects it from stomach acid. Also contributing to its success are several powerful flagella used to propel the pathogen through the thick mucus lining the stomach.

Pathogens produce a variety of substances that increase their success. Some bacteria produce **exotoxins**, strong poisons that are either secreted from the cell or leak out when the bacterial cell is destroyed. The toxin, not the presence of

Table 25-4 Important Bacterial Diseases and Their Causative Agents

Disease	Pathogen	Epidemiology/Comments
Anthrax	<i>Bacillus anthracis</i>	Most commonly occurs in domestic animals such as cattle. Can be transmitted to humans from infected animals or animal products. Endospores can live in soil for many years. Anthrax is not spread from person to person. Infection can occur in three ways: cutaneous, by inhalation, and gastrointestinal.
Antibiotic-associated diarrhea; and inflammation of colon	<i>Clostridium difficile</i> (common name: <i>C. dif</i>)	Risk greatest for older people taking antibiotics, people with compromised immune systems, and patients in hospitals and health care facilities for extended periods
Botulism	<i>Clostridium botulinum</i>	Contracted by eating foods that contain the exotoxin or from infected wound. Infant botulism is caused by ingesting endospores. Causes muscle paralysis and can cause death from respiratory failure.
Chlamydia	<i>Chlamydia trachomatis</i>	One of the most frequently reported sexually transmitted infections in the U.S. About 75% of infected women and 50% of infected men have no symptoms. If untreated, infection spreads and can lead to infertility. Chlamydia can also infect eyes; causes millions of cases of blindness worldwide each year.
Cholera	<i>Vibrio cholerae</i>	Contracted by eating food or drinking water contaminated with the bacteria. Common in areas with inadequate sewage treatment and impure water. Infects intestine and can cause severe diarrhea. Rapid fluid loss can lead to dehydration and death.
Diphtheria	<i>Corynebacterium diphtheriae</i>	Transmitted from person to person by intimate respiratory and physical contact. Endemic in developing countries. Not common in U.S. since vaccine became available in 1920s. Infects the heart muscle and respiratory passageways.
Epidemic typhus	<i>Rickettsia prowazekii</i>	Transmitted by infected body lice. After an 8- to 12-day incubation period, symptoms include fever, severe headache, muscle aches, and chills. Several days later, a rash appears. About 40% of untreated patients die.
Gonorrhea	<i>Neisseria gonorrhoeae</i>	Common sexually transmitted disease.
Hansen disease (leprosy)	<i>Mycobacterium leprae</i>	Thought to be spread from person to person in nasal secretions. Worldwide, this disease has disabled up to 2 million people.
Lyme disease	<i>Borrelia burgdorferi</i>	Transmitted to humans by bite of infected blacklegged ticks. Symptoms include skin rash, headache, fever, and fatigue. If untreated, infection can spread to joints, heart, and nervous system.
Peptic ulcer disease	<i>Helicobacter pylori</i>	Causes peptic ulcer, a lesion in the lining of the stomach or duodenum (upper part of small intestine).
Pertussis (whooping cough)	<i>Bordetella pertussis</i>	Highly communicable from person to person. Causes spasms of severe coughing. Vaccination available.
Plague	<i>Yersinia pestis</i>	Transmitted from wild rodents, squirrels, and cats to people by infected fleas. If untreated, can be fatal. Killed millions of people in Europe during the Middle Ages.
Pneumonia	<i>Streptococcus pneumoniae</i>	Transmitted from person to person. Strains of <i>S. pneumoniae</i> are resistant to some antibiotics. Incidence has decreased since introduction of a vaccine.
Salmonella (salmonellosis)	<i>Salmonella</i> sp.	Transmitted via contaminated chicken, eggs, or other food; also from feces of infected animals. Symptoms include fever, diarrhea, and stomach pain.
Syphilis	<i>Treponema pallidum</i>	Sexually transmitted disease passed through direct contact with a syphilis sore. If untreated, eventually damages brain, liver, bone, and spleen; can cause death.
Travelers' diarrhea	Certain strains of <i>Escherichia coli</i> are the most common cause.	Ingested in contaminated food and water. Affects 30% to 50% of travelers in high-risk areas (Central America, South America, Africa, Middle East, and most of Asia). Infecting bacteria produce toxins in gastrointestinal tract.
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Transmitted from person to person through inhalation of air containing the pathogen. Symptoms include fatigue, cough, fever, and weight loss. Not common in U.S., but multidrug-resistant form is a growing threat.
Typhoid fever	<i>Salmonella typhi</i>	Transmitted from person to person in food or water contaminated with feces. Risk greatest for travelers in developing countries, but vaccine available. Symptoms include high fever, headache, and loss of appetite. Can cause death if not treated.

the bacteria themselves, is responsible for the disease. Diphtheria is caused by a gram-positive bacillus (*Corynebacterium diphtheriae*) that produces a toxin only when lysogenized by a phage. The diphtheria toxin kills cells and causes inflammation.

Botulism, a type of food poisoning that can lead to paralysis and sometimes death, can result from eating improperly canned food. Botulism is caused by an exotoxin released by the gram-positive, endospore-forming *Clostridium botulinum*. During the canning process, food must be heated sufficiently to kill any highly heat-resistant endospores that may be present. If not, the endospores can germinate. The resulting bacterial population grows and releases an exotoxin so powerful that 1 g could kill one million humans! Like many exotoxins, the one that causes botulism is inactivated by heating. (Food must be heated to 80°C for 10 minutes or boiled for 3 to 4 minutes to inactivate the exotoxin.)

The botulism exotoxin, marketed under the trade name Botox, is used in extremely tiny amounts to treat several medical conditions involving spasms (involuntary muscle contractions). Botox injections are used to treat migraines, excessive sweating, overactive bladder/incontinence, and crossed eyes. Because Botox is a neurotoxin that works by paralyzing muscles, it can also relax facial wrinkles caused by contraction of the underlying muscles. However, its effects last for only about three months.

Another gram-positive, endospore-forming bacterium, *Clostridium difficile*, is an anaerobe that produces two exotoxins. It is a common cause of antibiotic-associated diarrhea (AAD), accounting for 15% to 25% of all episodes of AAD. *C. difficile* has recently become more virulent and more resistant to antibiotics. It has been linked to more than 500,000 cases and more than 29,000 deaths in the United States each year (see Table 25-4).

Figure 25-13 SEM of *Helicobacter pylori* attached to the epithelial lining of the stomach

Helicobacter pylori causes peptic ulcers.

Endotoxins are not secreted by pathogens but instead are components of the cell walls of most gram-negative bacteria. These compounds affect the host only when they are released from dead bacteria. Endotoxins bind to the host's macrophages (large phagocytic cells of the immune system) and stimulate them to release substances that cause fever and other symptoms of infection. Unlike exotoxins, which cause specific symptoms, endotoxins appear to affect the entire body. Endotoxins are not destroyed by heating.

Antibiotic resistance is a major public health problem

Bacteria mutate frequently and reproduce rapidly, often developing resistance to antibiotics. Many antibiotics target protein synthesis in bacteria. For example, streptomycin and related antibiotics block the initiation of protein synthesis. The tetracyclines block aminoacyl tRNA from binding to the A site on the ribosome.

Drug resistance may result from an accumulation of mutations in plasmid or chromosomal DNA. Plasmids that have genes for antibiotic resistance are called *R factors*. They have genes for resistance to a specific drug and for transferring the resistance to other bacteria. Some *R factors* have several genes for drug resistance, each encoding resistance to a different drug.

Methicillin-resistant *Staphylococcus aureus* (SA), referred to as MRSA, and vancomycin-resistant *Staphylococcus aureus*, or VRSA, have been directly linked to the horizontal transfer of antibiotic-resistance genes by plasmids during conjugation. An estimated 2 in every 100 healthy people in the United States now carries MRSA (FIG. 25-14). This “superbug” can cause infection in individuals with compromised immune systems. The Centers for Disease Control and Prevention estimates that MRSA causes more than 70,000 serious infections each year, resulting in death for many elderly and immune-compromised people. Overuse of antibiotics is the principal contributing factor to drug resistance. In any bacterial population, there are likely at least a few bacteria that are genetically resistant to a particular antibiotic. The bacteria that are *not*

Figure 25-14 Colorized SEM of methicillin-resistant *Staphylococcus aureus* (MRSA; purple) interacting with human white blood cells (blue)

These bacteria also show increased resistance to vancomycin. This strain of MRSA is a leading cause of infections associated with hospitals and nursing homes in the United States and United Kingdom.

resistant are killed by the antibiotic, leaving the resistant bacteria to multiply and produce a resistant population. Note that this process is a common, present-day example of natural selection.

The practice of feeding low-dose antibiotics to farm animals to promote growth has also resulted in many types of antibiotic-resistant bacteria that survive and multiply after susceptible bacteria are killed. Many countries have banned some antibiotics in animal feed. Antibiotic resistance has significantly reduced the effectiveness of most common, inexpensive antibiotics. Scientists and pharmaceutical companies are challenged to rapidly develop new antibiotics to treat bacterial infections that were formerly easily cured.

Another type of drug resistance explains why some infections, such as urinary tract infections, are difficult to cure. When *E. coli* infect the bladder, the immune system launches a powerful defense. The bacteria subvert the attack by forming *biofilms* (discussed earlier in this chapter). Each biofilm is surrounded by a matrix rich in polysaccharides and by a protective shell. The bacteria in the biofilm are resistant to antibiotics as well as to host defenses. By one estimate, bacteria growing in a biofilm are up to 1000 times as resistant to antibiotics as are the same type of bacteria that have not formed a biofilm. Within biofilms, differential gene expression and mutation lead to diverse bacterial colonies. The biofilm strategy also explains some other types of chronic or recurrent infections. A high percentage of infections acquired in hospitals involve biofilms.

CHECKPOINT 25.6

- **CONNECT** Why are Koch's postulates important?
- Contrast endotoxins with exotoxins.

Summary: Focus on Learning Objectives

25.1 The Structure of Bacteria and Archaea (page 518)

1 Describe the structure and common shapes of prokaryotic cells.

- Prokaryotic cells are very small and do not have membrane-enclosed organelles such as nuclei and mitochondria.
- Prokaryotic cells have several common shapes: spherical (**cocci**), rod-shaped (**bacilli**), and spiral. Spiral bacteria include the **spirillum**, which is a rigid helix, and **spirochete**, which is a flexible helix.

2 Compare the bacterial cell wall in gram-positive and gram-negative bacteria.

- Most bacteria have **cell walls** composed of **peptidoglycan**. The walls of **gram-positive** bacteria are very thick and consist mainly of peptidoglycan. The cell walls of **gram-negative** bacteria consist of a thin peptidoglycan layer and an outer membrane resembling the plasma membrane. Some species of bacteria produce a **capsule** or **slime layer** that surrounds the cell wall.
- Some prokaryotes have hairlike appendages called **fimbriae**. **Pili** also extend from the surface of some prokaryotes. Both fimbriae and pili help cells adhere to one another or to certain other surfaces, including cells they infect. *Cannulae* and *hami* are recently discovered hairlike appendages unique to archaea.

3 Describe movement in prokaryotes and describe the structure of the bacterial flagellum.

- Bacterial **flagella** are structurally different from eukaryotic flagella; each flagellum consists of a basal body, hook, and filament. They produce a rotary motion. Many archaea have an *archaellum* that functions similarly to the bacterial flagellum.

25.2 Prokaryote Reproduction and Evolution (page 522)

4 Describe asexual reproduction in prokaryotes and summarize three mechanisms (transformation, transduction, and conjugation) that may lead to genetic recombination.

- The genetic material of a bacterium typically consists of a circular DNA molecule and one or more **plasmids**, smaller circular fragments of DNA.
- Prokaryotes reproduce asexually by **binary fission** (the cell divides, forming two cells), **budding** (a bud forms and separates from the mother cell), or **fragmentation** (walls form inside the cell, which then separates into several cells).
- In prokaryotes, genetic material can be exchanged by transformation, transduction, or conjugation. In **transformation**, a prokaryotic cell takes in foreign DNA released by another cell. Homologous segments of foreign and host DNA are exchanged. In **transduction**, a phage carries bacterial DNA from one bacterial cell into another. In **conjugation**, a donor cell transfers plasmid DNA to a recipient cell.

5 State specific factors that contribute to the rapid evolution of bacteria and archaea.

- Rapid reproduction ensures that mutations are rapidly passed to new generations. **Horizontal gene transfer**—by transformation, transduction, or conjugation—contributes to rapid evolution in prokaryotes.

25.3 Nutritional and Metabolic Adaptations (page 524)

6 Describe the principal modes by which prokaryotes carry on nutrition and energy capture, and compare their requirements for oxygen.

- Most prokaryotes are **heterotrophs** that obtain carbon from other organisms; some are **autotrophs** that make their own organic molecules from simple raw materials.
- Chemotrophs** obtain energy from chemical compounds; **phototrophs** capture energy from light.
- Autotrophs may be **photoautotrophs**, which obtain energy from sunlight, or **chemoautotrophs**, which obtain energy by oxidizing inorganic chemicals such as ammonia.
- Photoheterotrophs** obtain carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight. The majority of bacteria are **chemoheterotrophs**. They are mainly free-living **decomposers** that obtain both carbon and energy from dead organic matter.
- Most bacteria are **aerobic**; that is, they require oxygen for cellular respiration. Some prokaryotes are **facultative anaerobes** that metabolize anaerobically when necessary; others are **obligate anaerobes** that can carry on metabolism only anaerobically.
- Some bacteria and archaea carry on **nitrogen fixation**; that is, they reduce nitrogen in the atmosphere to ammonia. Other prokaryotes convert ammonia to nitrite or nitrate in a process called **nitrification**.

25.4 The Phylogeny of the Two Prokaryote Domains (page 525)

7 Compare characteristics of the three domains: Archaea, Bacteria, and Eukarya.

- Prokaryotes are assigned to domain **Archaea** and domain **Bacteria**.
- Unlike those of bacteria, the cell walls of archaea do not have peptidoglycan. The translational mechanisms of eukaryotes more closely resemble those of archaea than those of bacteria.

8 Distinguish between the main groups of archaea and identify specific types of archaea belonging to each group (see Fig. 25-9).

- The **Crenarchaeota** include many **extreme thermophiles**, archaea that can inhabit very hot, sometimes acidic, environments and archaea that are marine dwellers. **Euryarchaeota** include methanogens, extreme halophiles, and some extreme thermophiles. **Methanogens** are obligate anaerobes that produce methane gas from simple carbon compounds. **Extreme halophiles** inhabit saturated salt solutions. **Korarchaeota** have been found in terrestrial hot springs. **Nanoarchaeota** include extreme thermophiles.

- Two supergroups have recently been proposed: “TACK” and the “Asgard” clade, which includes Lokiarchaeota. There is some evidence that this group gave rise to the eukaryotes.

9 Describe the main groups of bacteria discussed in this chapter.

- Major groups of bacteria include proteobacteria, gram-positive bacteria, cyanobacteria, chlamydias, and spirochetes (see Table 25-3).

25.5 Impact on Ecology, Technology, and Commerce (page 528)

10 Identify the critical ecological roles played by prokaryotes and briefly describe their relationships with other organisms.

- Prokaryotes form intimate relationships with other organisms. All plants and animals have a community of microorganisms referred to as **microbiota**. The human **microbiome** consists of more than 10,000 different microorganisms.
- Many bacteria are symbiotic with other organisms. **Mutualism** is a symbiotic relationship in which both partners benefit. In **commensalism**, one partner benefits, and the other is neither harmed nor helped. In **parasitism**, the **parasite** benefits, and the host is harmed. Bacterial **pathogens** cause disease, but are usually not considered obligate parasites. **Biofilms** are dense communities of microorganisms, in which cells adhere to one another on a surface. Biofilms may include bacteria, archaea, protists, and fungi.
- Prokaryotes play essential ecological roles as decomposers and are important in recycling nitrogen and other nutrients. Some bacteria carry out photosynthesis.

11 Describe some of the important roles played by prokaryotes in commerce and technology.

- Some prokaryotes produce antibiotics. We have developed the technology for using certain bacteria to produce vaccines, insulin, and other important compounds. We use bacteria in the production of many foods, including cheese, yogurt, vinegar, and chocolate. We also use microbes in sewage treatment and in bioremediation.

25.6 Bacteria and Disease (page 533)

12 Describe the roles played by Louis Pasteur and Robert Koch in understanding infectious disease; list Koch's postulates.

- Louis Pasteur demonstrated that sterilization prevented bacterial growth. **Koch's postulates** are a set of guidelines developed by Robert Koch to demonstrate that a specific pathogen causes specific disease symptoms: (1) the pathogen must be present in every individual with the disease, (2) a sample of the microorganism taken from the diseased host can be grown in pure culture, (3) a sample of the pure culture causes the same disease when injected into a healthy host, and (4) the microorganism can be recovered from the experimentally infected host.

13 Identify adaptations that have contributed to pathogen success.

- Some pathogenic bacteria release strong poisons called **exotoxins**; others produce **endotoxins**, poisonous components of their cell walls that are released when bacteria die. Many bacteria have become resistant to antibiotics. Plasmids that have genes for antibiotic resistance are called *R factors*. See Table 25-4 for a description of some pathogenic bacteria.

Test Your Understanding

Know and Comprehend

1. Peptidoglycan is a chemical compound found in the cell walls of (a) most viroids (b) most archaea (c) all prokaryotes (d) most bacteria (e) most eukarya
2. Bacterial flagella (a) are homologous with eukaryotic flagella (b) exhibit a rotary motion (c) consist of a basal body and nine pairs of microtubules (d) are important in transduction (e) are characteristic of gram-positive bacteria
3. Endospores (a) are formed by some viruses (b) are extremely durable cells (c) are comparable to the reproductive spores of fungi and plants (d) cause fever and other symptoms in the host (e) are vulnerable to infection by archaea
4. In conjugation, (a) two bacterial cells of different mating types come together, and genetic material is transferred from one to another (b) a bacterial cell develops a bulge that enlarges and eventually separates from the mother cell (c) fragments of DNA released by a broken cell are taken in by another bacterial cell (d) a phage carries bacterial genes from one bacterial cell into another (e) walls develop in the cell, which then divides into several new cells
5. The majority of heterotrophic bacteria are (a) free-living chemoheterotrophs (b) photoautotrophs (c) chemoautotrophs (d) facultative anaerobes (e) obligate anaerobes
6. Bacteria that are autotrophs (a) do not require atmospheric oxygen for cellular respiration (b) must obtain organic compounds from other organisms (c) manufacture their own organic molecules from simple raw materials (d) get their nourishment from dead organisms (e) produce endospores when oxygen levels are too low for active growth
7. Bacteria that thrive in puncture wounds are likely to be (a) aerobes (b) photoautotrophs (c) chemoautotrophs (d) endospores (e) obligate anaerobes
8. Which of the following do *not* belong to domain Archaea? (a) prokaryotes that produce methane from carbon dioxide and hydrogen (b) thermophiles (c) halophiles (d) bacteriophages (e) prokaryotes with cell walls that lack peptidoglycan
9. Rhizobial bacteria (a) are used in the production of yogurt (b) produce antibiotics (c) cause peptic ulcers (d) are the pathogens that cause syphilis (e) form mutualistic relationships with the roots of legumes and fix nitrogen
10. Robert Koch (a) proposed a set of guidelines to demonstrate that a specific pathogen causes specific disease symptoms (b) discovered *Helicobacter* (c) showed that biofilms consist of microorganisms (d) proposed a hypothesis for antibiotic resistance (e) demonstrated that people can be stimulated to develop immunity to disease
11. Which group of bacteria contains the gram-positive, anaerobic bacterium that causes botulism? (a) clostridia (b) actinomycetes (c) enterobacteria (d) spirochetes (e) streptococci

Apply and Analyze

12. **VISUALIZE** Label the diagram.

13. Imagine that you discover a new microorganism. After careful study you determine that it should be classified in domain Archaea. What characteristics might lead you to this decision?

Evaluate and Synthesize

14. What would be the consequences for eukaryotes if all prokaryotes suddenly became extinct?
15. **EVOLUTION LINK** In what way does the use of antibiotics impose selective pressure on bacteria?
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** The Centers for Disease Control and Prevention considers antibiotic resistance to be one of the world's most pressing health problems. How can scientists help solve this problem? (Consider both technology and the general public.)

26 Protists

Protists are an informal group of primarily aquatic eukaryotic organisms with diverse body forms, types of reproduction, modes of nutrition, and lifestyles. Protists, which include algae, water molds, slime molds, and protozoa, are unicellular, colonial, or simple multicellular organisms that have a eukaryotic cell organization (see photograph). The word *protist*, from the Greek for “the very first,” reflects the idea that protists were the first eukaryotes to evolve.

Protists are members of domain Eukarya, the third domain on the tree of life. (Recall the three domains depicted in Figure 23-2.) Eukaryotic cells are characteristic of protists as well as of complex multicellular organisms belonging to the kingdoms Fungi, Animalia, and Plantae. However, having a eukaryotic cell structure clearly differentiates protists from members of the prokaryotic domains Bacteria and Archaea. Recall from Chapter 4 that unlike prokaryotic cells, eukaryotic cells have nuclei and other membrane-enclosed organelles such as mitochondria and plastids, 9 + 2 flagella, and multiple chromosomes in which DNA and proteins form a complex called chromatin. Sexual reproduction, meiosis, and mitosis are also characteristic of eukaryotes.

Until recently, all protists were classified as the kingdom Protista, but this classification was by default: protists included any eukaryotes that were not land plants, fungi, or animals. Based largely on recent molecular data that have clarified many evolutionary relationships among eukaryotes, kingdom Protista

PHOTO: LM of a pair of green algal cells (*Micrasterias*) produced by mitosis. Green algae are closely related to land plants.
Marek Mis/Science Source

KEY CONCEPTS

- 26.1** Protists are a diverse group of eukaryotic organisms that vary in body plan (unicellular, colonial, coenocytic, multicellular), method of motility (pseudopodia, cilia, flagella), nutrition type (autotrophic, heterotrophic), and mode of reproduction (asexual, sexual).
- 26.2** Much uncertainty surrounds eukaryote evolution, but eukaryote organelles such as chloroplasts probably descended from engulfed cells that survived and became organelles. Current scientific evidence supports splitting the protists and other eukaryotes (land plants, fungi, and animals) into five informal “supergroups.”
- 26.3** Excavates are a supergroup of unicellular protists with atypical, greatly modified mitochondria; they get their name because many have a deep, or excavated, oral groove.
- 26.4** Chromalveolates are a supergroup of diverse protists that may have originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga.
- 26.5** Rhizarians are a supergroup of amoeboid cells that often have tests (shells) through which cytoplasmic projections extend; forams, actinopods, and certain shell-less amoebas are rhizarians.
- 26.6** Archaeplastids are a supergroup that includes red algae, green algae, and land plants, all of which have plastids enclosed by two external membranes.
- 26.7** Unikonts are a supergroup that includes amoebozoa and choanoflagellates as well as fungi and animals.

is no longer a recognized clade. Although we have made great progress in understanding the evolutionary relationships among protists, many relationships remain uncertain.

Biologists currently recognize dozens of protist taxa, which, along with other eukaryotes, are classified into five “supergroups.” Consideration of all protist taxa is beyond the scope of this text, but we discuss several representative examples of each supergroup and provide insights into how such diverse eukaryotes may have evolved.

26.1 Diversity in the Protists

LEARNING OBJECTIVE

- 1 Discuss in general terms the diversity inherent in protists, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.

Because of their huge numbers, protists are crucial to the natural balance of the living world. Protists are an important source of food for other organisms, and photosynthetic protists supply oxygen to aquatic and terrestrial ecosystems. Certain protists are economically important, and others cause devastating diseases such as malaria.

Body plan varies considerably among protists. Most protists are *unicellular*, with each cell forming a complete organism capable of performing all the functions characteristic of life. Some protists form **colonies**, loosely connected groups of cells; some are **coenocytes**, consisting of a multinucleate mass of cytoplasm; and some are *multicellular*, composed of many cells. Unlike animals, plants, and many fungi, most multicellular protists have relatively simple body forms without specialized tissues.

Size and structural complexity are not the only variable features of protists. During the course of the long evolutionary history of protists, diversity has evolved in their means of locomotion, ways of obtaining nutrients, interactions with other organisms, habitats, and modes of reproduction.

Protists, most of which are motile at some point in their life cycle, have various means of locomotion. Some move by pushing out cytoplasmic extensions called **pseudopodia** along the leading edge and retracting the cytoplasm that trails behind, as an amoeba does. Other protists move by flexing individual cells; by gliding over surfaces; by waving **cilia**, short, hairlike organelles; or by lashing **flagella**, long, whiplike organelles. Some protists have two or more means of locomotion, such as both flagella and pseudopodia.

Methods of obtaining nutrients differ widely among protists. Most algae are autotrophic and photosynthesize as plants do (FIG. 26-1a). Some heterotrophic protists obtain their nutrients by absorption, as fungi do, whereas others resemble animals in that they ingest food. Some protists switch their modes of nutrition and are autotrophic at certain times and heterotrophic at others.

Although many protists are free-living, others form stable symbiotic associations with unrelated organisms. These intimate associations range from **mutualism**, a more or less equal partnership where both partners benefit; to **commensalism**, where one partner benefits and the other is unaffected; to **parasitism**,

where one partner (the parasite) lives on or in another (the host) and metabolically depends on it (see Chapter 54). Some parasitic protists are important *pathogens* (disease-causing agents) of plants or animals. Throughout this chapter, we describe specific examples of symbiotic associations involving protists.

Most protists are aquatic and live in the ocean or in freshwater streams, lakes, and ponds (FIG. 26-1b). They make up most of the **plankton**, the floating, often microscopic

(a) *Chlamydomonas* is a photosynthetic organism with two flagella and a cup-shaped chloroplast.

(b) Protists in a drop of pond water. Several modes of locomotion are shown.

Figure 26-1 Protists

organisms that inhabit surface waters and are the base of the food web in aquatic ecosystems. Other aquatic protists attach to rocks or other surfaces in the water. Even parasitic protists are aquatic because they live in the watery environments of other organisms' body fluids. Terrestrial protists are restricted to damp places such as soil, cracks in bark, and leaf litter.

Reproduction is varied among protists. Almost all protists reproduce asexually, and many also reproduce sexually. However, most protists do not develop multicellular reproductive organs, nor do they form embryos the way more complex organisms do.

CHECKPOINT 26.1

- How do protists vary in their means of obtaining nutrients?
- What are some of the ways protists interact with other organisms?

26.2 How Did Eukaryotes Evolve?

LEARNING OBJECTIVES

- 2 Discuss the hypothesis of serial endosymbiosis and briefly explain some of the evidence that supports it.
- 3 Describe the kinds of data biologists use to classify eukaryotes.

For many years biologists have hypothesized that protists were the first eukaryotic cells and that they evolved from ancestral prokaryotes. However, the more we study eukaryote origins, the more uncertain we are. One thing we can say with absolute certainty is that the evolution of eukaryotes was a complex process.

Eukaryotes may have appeared in the fossil record as early as 2.2 billion years ago. Other than a few protists with hard shells, such as diatoms and forams, most ancient protists did not leave many fossils because their bodies were too soft to leave permanent traces. Evolutionary studies of protists focus primarily on molecular and structural comparisons of present-day organisms, which contain many clues about their evolutionary history.

Mitochondria and chloroplasts probably originated from endosymbionts

Throughout evolutionary history, one organism has engulfed another to the mutual benefit of both. According to the hypothesis of **serial endosymbiosis**, certain eukaryotic organelles, particularly mitochondria and chloroplasts, arose from symbiotic relationships between larger cells and smaller bacteria that were incorporated and lived within them. (You might want to review serial endosymbiosis in Figure 21-8.) Cell biologists hypothesize that mitochondria originated from aerobic bacteria. Studies of mitochondrial DNA suggest that it is a remnant from the mitochondrion's past, when it was an independent organism. Ribosomal RNA (rRNA) sequences from mitochondria closely match rRNAs found in purple bacteria, suggesting that ancient purple bacteria were the ancestors of mitochondria.

Chloroplast evolution is more complex given that there were probably several endosymbiotic events (**FIG. 26-2**). Molecular evidence supports the view that incorporation of an ancient cyanobacterium within a host cell, known as *primary endosymbiosis*, resulted in the chloroplasts in today's red algae, green algae, and land plants. (The host cell was eukaryotic because mitochondria almost certainly evolved before chloroplasts.) Biologists hypothesize that these chloroplasts, which are enclosed by two external membranes (known as the outer and inner chloroplast membranes; see Chapter 9), later provided other eukaryotes with their chloroplasts during *secondary endosymbiosis*.

Secondary endosymbiosis occurred frequently in eukaryote evolution, as evidenced by the presence of additional chloroplast membranes. For example, *three* membranes envelop the chloroplasts of euglenoids and dinoflagellates, and *four* membranes surround the chloroplasts of diatoms, golden algae, and brown algae. Understanding how these membranes originated is an essential aspect of serial endosymbiosis, and many researchers are studying the origin of chloroplasts in different organisms.

Even non-photosynthetic protists may contain chloroplast relics from secondary endosymbiotic events. Apicomplexans—protists such as *Plasmodium*, which causes malaria—have a non-photosynthetic chloroplast derived from a red alga, surrounded by four external membranes. Because this plastid carries out certain functions essential to the survival of the parasite, it has become a target of ongoing research focused on the development of antimalarial drugs.

A consensus in eukaryote classification is beginning to emerge

Scientists re-evaluate evolutionary relationships among the eukaryotes as additional evidence becomes available. Two types of modern research, molecular analysis and ultrastructural studies, have contributed substantially to scientific understanding of the phylogenetic relationships among protists. Molecular data were initially obtained for the gene that codes for small subunit ribosomal RNA in different eukaryotes (SSU rRNA; see Chapter 25). More recently, biologists have compared other nuclear genes, many of which code for proteins, in different protist taxa.

Ultrastructure is the fine details of cell structure revealed by electron microscopy. In many cases, ultrastructure data complement molecular data. Electron microscopy reveals similar structural patterns among those protist taxa that comparative molecular evidence suggests are **monophyletic**; that is, they evolved from a common ancestor (see Chapter 23). For example, molecular and ultrastructure data suggest that water molds, diatoms, golden algae, and brown algae—protist taxa that at first glance seem to share few characteristics—are a monophyletic group.

Given the diversity in protist ultrastructure and molecular data, biologists regard the protists as a **paraphyletic group**; that is, protists contain some, but not all, of the descendants of a common eukaryote ancestor. Molecular and ultrastructural analyses continue to help biologists clarify relationships among the various protist phyla and among protists and the other eukaryotic kingdoms.

Biologists use these data to develop various classification schemes. A current scheme that is used in this edition

Scientists hypothesize that plastids have evolved through both primary and secondary endosymbiosis.

Figure 26-2 Chloroplast evolution by primary and secondary endosymbiosis

CONNECT How many external membranes are present in a land plant chloroplast? Use Figure 9-4b to check your answer.

splits the protists and other eukaryotes (land plants, fungi, and animals) into five informal supergroups (**FIG. 26-3** and **TABLE 26-1**). This classification scheme will almost certainly be modified as new information becomes available.

Now that we have a basic understanding of evolution of the protists and other eukaryotes, let's examine representative protists within the five supergroups.

CHECKPOINT 26.2

- How does serial endosymbiosis explain the origin of chloroplasts?
- What kinds of scientific evidence support the hypothesis that protists are a paraphyletic group?

Key Point

Unraveling phylogenetic relationships among the protists has been difficult, but progress is occurring. Many biologists currently classify eukaryotes into five major “supergroups.”

Figure 26-3 Evolutionary relationships among eukaryotes

This evolutionary tree presents one interpretation of relationships among eukaryotes in which the eukaryotes are placed in five “supergroups.” Organisms within ovals represent separate eukaryotic kingdoms discussed in later chapters. All other eukaryotes are informally known as protists, a paraphyletic group. At node A, all five supergroups branch from the same point, indicating that the branching order is unresolved at this time. The same is true at node B for the diatoms, brown algae, and golden algae. Based on Keeling, P.J., “Deep Questions in the Tree of Life,” *Science*, Vol. 317 (2007): 1875–1876.

CONNECT Where on the cladogram would you place the common ancestor of brown algae and water molds? The common ancestor of animals and fungi?

Table 26-1 “Protist” Clades

Eukaryote “Supergroup”	Representative “Protist” Clades	Key Characters
EXCAVATES Unicellular protists with atypical, greatly modified mitochondria; bikonts	Diplomonads and parabasalids Euglenoids and trypanosomes	Two or more flagella; ventral oral (feeding) groove Some with plastids; crystalline rod in flagella
CHROMALVEOLATES Diverse protists that may have originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga; bikonts	Alveolates Dinoflagellates, ciliates, apicomplexans Stramenopiles Water molds, diatoms, brown algae, golden algae	Alveoli (flattened vesicles) just inside the plasma membrane Most have two flagella, one with hairs; no flagella in some
RHIZARIANS Amoeboid cells that often have tests (shells); bikonts	Forams Actinopods	Porous tests (hard shells) through which cytoplasmic projections (pseudopods) extend Endoskeletons (internal shells) through which axopods (filamentous pseudopods) extend
ARCHAEPLASTIDS Plastids bounded by outer and inner membranes; include land plants; bikonts	Red algae Green algae	Chloroplast pigments include phycoerythrin (red pigment) and phycocyanin (blue pigment) Chloroplast pigments identical to those in land plants
UNIKONTS Cells that have a single flagellum or are amoebas with no flagella; have a triple-gene fusion that is lacking in other eukaryotes; include animals and fungi	Amoebozoa Amoebas, plasmodial slime molds, cellular slime molds Opisthokonts Choanoflagellates	Naked amoebas (no tests) with lobelike pseudopods No flagella or single posterior flagellum on motile cells

26.3 Excavates

LEARNING OBJECTIVE

- 4 Summarize the basic features of excavates and distinguish among diplomonads, parabasalids, and euglenoids.

Excavates are a diverse group of unicellular protists with flagella. These protists are so named because many have a deep, or *excavated*, oral groove. Unlike other protists, excavates have atypical, greatly modified mitochondria. Many excavates are endosymbionts and live in anoxic (without oxygen) environments. These excavates do not carry out aerobic respiration; they obtain energy by the anaerobic pathway of glycolysis (presumably by fermentation).

Currently, excavates include diplomonads, parabasalids, euglenoids, and trypanosomes. The inclusion of these organisms into a single superfamily is somewhat controversial because their relationships to one another are uncertain. Additional studies are needed to determine if the excavates as currently presented are a monophyletic group.

Diplomonads are small, mostly parasitic flagellates

Diplomonads are excavates that have one or two nuclei, no functional mitochondria, no Golgi complex, and up to eight flagella. *Giardia* is a parasitic diplomonad (FIG. 26-4a). Interestingly, *Giardia* has two haploid nuclei, each of which contains a complete copy of *Giardia*’s genome. *Giardia* lacks

functional mitochondria, although it contains certain genes that code for proteins associated with mitochondria in other organisms. *Giardia* also has reduced structures that somewhat resemble mitochondria. This information suggests to some biologists that an early eukaryotic ancestor of *Giardia* may have possessed mitochondria, which were somehow lost or reduced at a later time during its evolutionary history.

Giardia intestinalis is a major cause of water-borne diarrhea throughout the world. *Giardia* is eliminated as a resistant cyst in the feces of many vertebrate animals. These cysts are a common contaminant in untreated drinking water, even in environments considered relatively pristine, such as isolated mountain streams. In a heavy infection, much of the wall of the small intestine is coated with these flagellates, which interfere with the absorption of digested nutrients and cause weight loss, abdominal cramps, and diarrhea.

Parabasilids are anaerobic endosymbionts that live in animals

Parabasilids are anaerobic, flagellated excavates that often live in animals. Trichonymphs and trichomonads are examples of parabasilids. *Trichonymphs*, which have hundreds of flagella, live in the guts of termites and wood-eating cockroaches (FIG. 26-4b). Trichonymphs ingest wood chips from the wood that termites or roaches eat. The trichonymphs rely on endosymbiotic bacteria to digest cellulose in the wood. Thus, in an excellent example of mutualism, the insects, trichonymphs, and bacteria all obtain their nutrients from cellulose.

The most well-known trichomonad is probably *Trichomonas vaginalis*, which causes trichomoniasis, a curable sexually

Figure 26-4 Diplomonads and parabasalids

transmitted disease (STD) in humans. Trichomoniasis affects both men and women, although the symptoms are more obvious in women. According to the Centers for Disease Control and Prevention, about 7.4 million new cases occur in the United States each year.

Euglenoids and trypanosomes include both free-living species and parasites

Euglenoids and *trypanosomes* are characterized by an unusual flagellum: in addition to the 9 + 2 arrangement of microtubules characteristic of all eukaryotic flagella, these excavates have a crystalline rod in their flagella; the function of this rod is unknown. Like other excavates, euglenoids and trypanosomes also have atypical mitochondria.

Most **euglenoids** are unicellular flagellates, and about one-third of them are photosynthetic (FIGS. 26-5a and b). They generally have two flagella: one long and whiplike and one that is often so short that it does not extend outside the cell. Some euglenoids, such as *Euglena*, change shape continually as they move through the water because their **pellicle**, or outer covering, is flexible.

Autotrophic euglenoids have chloroplasts with the same photosynthetic pigments that green algae and plants have. However, these chloroplasts were acquired by secondary endosymbiosis; euglenoids are not closely related to either group, as shown in Figure 26-3. Some photosynthetic euglenoids lose their chlorophyll when grown in the dark, and they

obtain their nutrients heterotrophically, by ingesting organic matter. Other euglenoids are always colorless and heterotrophic. Some heterotrophic species absorb organic compounds from the surrounding water, whereas others engulf bacteria and protists by **phagocytosis**; they digest the prey within food vacuoles.

Trypanosomes are excavates with a single mitochondrion that has an organized deposit of DNA called a **kinetoplastid**. Trypanosomes are colorless, and many are parasitic and cause disease. In vertebrates, including humans, trypanosomes live in the blood. For example, *Trypanosoma brucei* is a human parasite that causes African sleeping sickness (FIG. 26-5c). It is transmitted by the bite of infected tsetse flies. Early symptoms include recurring attacks of fever. Later, when the trypanosomes have invaded the central nervous system, infected people are lethargic, have difficulty speaking or walking, and may die if the disease is untreated. Control efforts are showing significant success; the incidence of the disease has dropped from about 300,000 new cases in 1998 to an estimate of below 20,000 in 2014.

CHECKPOINT 26.3

- What cell organelle is atypical in excavates?
- Give an example of a human disease caused by each of the following: diplomonads, parabasalids, and trypanosomes.

(a) LM of *Euglena gracilis*, a unicellular, flagellate euglenoid.

(b) *Euglena's* pellicle is flexible and changes shape easily. The eyespot may shield a light detector at the base of the long flagellum, thereby helping *Euglena* move to light of an appropriate intensity.

(c) SEM of the flagellate *Trypanosoma brucei* among human red blood cells. *Trypanosoma brucei* causes African sleeping sickness in humans.

26.4 Chromalveolates

LEARNING OBJECTIVES

- 5 Contrast the two main groups of chromalveolates: alveolates and stramenopiles.
- 6 Distinguish among the alveolates: dinoflagellates, apicomplexans, and ciliates.
- 7 Distinguish among the stramenopiles: water molds, diatoms, golden algae, and brown algae.

The **chromalveolates** are a supergroup composed of extremely diverse protists with few shared characters. Chromalveolates probably originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga (which itself was the result of primary endosymbiosis). Most chromalveolates are photosynthetic, and evidence suggests that heterotrophic chromalveolates, such as the water molds and ciliates, descended from autotrophic ancestors. Classification of the chromalveolates as a monophyletic supergroup is controversial because some DNA sequence data have indicated that they are not monophyletic. The chromalveolates are divided into two main groups: alveolates and stramenopiles.

The unifying features of protists classified as **alveolates** include similar ribosomal DNA sequences and **alveoli** (sing., *alveolus*), flattened vesicles located just inside

the plasma membrane. In some alveolates the vesicles contain plates of cellulose. Alveolates include the dinoflagellates, apicomplexans, and ciliates.

The **stramenopiles** include water molds, diatoms, golden algae, and brown algae. At first glance stramenopiles appear too diverse to classify together. However, most stramenopiles have motile cells with two flagella, one of which has tiny hairlike projections extending from the shaft. The word *stramenopile* comes from Latin words referring to “straw” (i.e., the shaft of the flagellum) and “hairs.”

Most dinoflagellates are a part of marine plankton

Dinoflagellates are generally unicellular, although a few are colonial. Their alveoli contain interlocking cellulose plates impregnated with silicates. The typical dinoflagellate has two flagella. One flagellum wraps around a transverse groove in the center of the cell like a belt, and the other lies in a longitudinal groove (perpendicular to the transverse groove), projecting behind the cell (FIG. 26-6a). The undulation of these flagella propels the dinoflagellate through the water like a spinning top. Indeed, the name is derived from the Greek *dinos*, meaning “whirling.” Many marine dinoflagellates are bioluminescent.

Many dinoflagellates are photosynthetic, but others are heterotrophic and ingest other microorganisms for food. Some dinoflagellates are endosymbionts that live in the

Figure 26-6 Dinoflagellates

bodies of marine invertebrates such as mollusks, jellyfish, and corals (see Fig. 54-12). These symbiotic dinoflagellates, called **zooxanthellae**, photosynthesize and provide carbohydrates for their invertebrate partners. Zooxanthellae contribute substantially to the productivity of coral reefs. Other dinoflagellates that are endosymbionts lack pigments and are parasites that live off their hosts.

Ecologically, dinoflagellates are important producers in marine ecosystems. A few dinoflagellates are known to have occasional population explosions, or blooms. These blooms, known as **red tides**, frequently color coastal waters orange, red, or brown (FIG. 26-6b). Dinoflagellate blooms are particularly common in warm, nutrient-enriched water. Some dinoflagellate species that form red tides produce a toxin that attacks the nervous systems of fishes, leading to fish kills. Birds sometimes die after eating contaminated fish. Research has also linked red tides to manatee and dolphin deaths in Florida.

Apicomplexans are spore-forming parasites of animals

Apicomplexans are a large group of parasitic, spore-forming alveolates, some of which cause serious diseases in humans. As discussed earlier in the chapter, they contain the unpigmented remnant of a chloroplast derived from a red alga. Apicomplexans lack specific structures for locomotion (cilia, flagella, or pseudopodia) and move by flexing.

Apicomplexans have an *apical complex* of microtubules that attaches the parasite to its host cell; the apical complex is visible only by using electron microscopy. They also have the ability to form a structure known as a *moving junction*, which enables them to form a vacuole that encloses and protects them as they invade a host cell. At some stage in their life cycle, apicomplexans produce **sporozoites**, small infective agents transmitted to the next host. Many apicomplexans spend part of their complex life cycle in one host species and part in a different host species.

Malaria is caused by an apicomplexan (FIG. 26-7). According to the World Health Organization, there were approximately 212 million new cases of malaria worldwide in 2015; about 429,000 people, mostly children in developing countries, died from the disease. Although for centuries Chinese, Greek, Arabic, and Roman writings described the disease, its causative agent and mode of transmission by means of mosquitoes were not identified until the end of the 19th century. British scientist Ronald Ross received the Nobel Prize in Physiology or Medicine in 1902 for his role in elucidating the life cycle of *Plasmodium*, the apicomplexan that causes malaria.

Control measures that have lost effectiveness due to the evolution of chemotherapy resistance on the part of *Plasmodium* and pesticide resistance on the part of the mosquitoes are currently being replaced by newer methods, but the battle is ongoing. For example, chemotherapies that include the drug artemisinin in combination with other drugs have emerged as the standard of care, but there are signs that resistance of the parasite to artemisinin is beginning to evolve in some countries. Researchers

Figure 26-7 Life cycle of *Plasmodium*, the causative agent of malaria

Plasmodium, an apicomplexan, lives in two hosts: mosquitoes and humans. The inset shows a TEM of a colorized human red blood cell filled with merozoites.

are currently testing new antimalarial drugs and several possible vaccines against malaria. Advanced sequencing of the genomes of *P. falciparum* and the *Anopheles* mosquito may lead to new diagnostics, drugs, and vaccines.

Ciliates use cilia for locomotion

Ciliates are among the most complex of eukaryotic cells. These unicellular alveolates have a pellicle that gives them a definite but changeable shape. In *Paramecium* the surface of the cell is covered with several thousand fine, short, hair-like cilia that extend through pores in the pellicle to facilitate movement (FIGS. 26-8a and b; also see Fig. 4-5c). The cilia beat with such precise coordination that the organism can back up and turn around as well as move forward.

Not all ciliates are motile. Some sessile forms have stalks, and others, although capable of some swimming, are more likely to remain attached to a rock or other surface at one spot. Their cilia set up water currents that draw food toward them.

Ciliates differ from other protists in having two kinds of nuclei: one or more small, diploid **micronuclei** that function in reproduction; and a larger, polyploid **macronucleus** that controls cell metabolism and growth. Most ciliates are capable of a sexual process called **conjugation**, in which two individuals come together and exchange genetic material (FIG. 26-8c). Conjugation results in two “new” cells that are genetically identical to each other but different from what they were before conjugation. Mitosis and cell division need not follow immediately after conjugation. Ciliates usually divide perpendicularly to their longitudinal axis.

(a) Note the complex cell structure in this interference-contrast LM of *Paramecium*, a freshwater ciliate. Like many ciliates, *Paramecium* has multiple nuclei: a macronucleus and one or more smaller micronuclei.

(b) Food particles are swept into *Paramecium*'s ciliated oral groove and incorporated into food vacuoles. Lysosomes fuse with the food vacuoles, and the food is digested and absorbed; undigested wastes are eliminated through the anal pore.

(c) Conjugation in *Paramecium caudatum*.

Figure 26-8 Ciliates

Water molds produce biflagellate reproductive cells

Water molds are stramenopiles that were once classified as fungi because of their superficial resemblance. Both water molds and fungi have a body, called a **mycelium**, that grows over organic material, digesting it and then absorbing the predigested nutrients (FIG. 26-9). The threadlike **hyphae** that

make up the mycelium in water molds are *coenocytic*, meaning that there are no cross walls; the body consists of a single multinucleate cell. The cell walls of water molds are composed of cellulose (as in plants), chitin (as in fungi), or both.

When food is plentiful and environmental conditions are favorable, water molds reproduce asexually. A hyphal tip swells, and a cross wall is formed, separating the hyphal tip from the rest of the mycelium. Within this structure, called a **zoosporangium**,

Figure 26-9 Water molds

The life cycle of *Saprolegnia*, a water mold. *Inset:* A mycelium of *Saprolegnia* radiates from a dead insect.

tiny biflagellate **zoospores** form, each of which swims about, lands and encysts, and eventually develops into a new mycelium. When environmental conditions worsen, water molds initiate sexual reproduction. After fusion of male and female nuclei, thick-walled **oospores** develop from the oospheres (female gametes). Water molds often spend the winter as oospores.

Some water molds have played a profound role in human history. For example, the Irish potato famine of the 19th century was precipitated by the water mold *Phytophthora infestans*, which causes late blight of potatoes. (The genus *Phytophthora* is named from Greek words meaning “plant destruction.”) During several rainy, cool summers in Ireland

in the 1840s, the water mold multiplied unchecked, causing potato tubers to rot in the fields. Because potatoes were the staple of the Irish peasants’ diet, as many as one million people starved. The famine prompted a mass migration out of Ireland to the United States and other countries.

A close relative of the late blight water mold, *P. ramorum*, causes sudden oak death, which is killing oak forests in several western states. Plant pathologists are concerned that the disease may spread to midwestern and eastern forests. This particular water mold also attacks redwoods, Douglas firs, bay trees, maples, and several other plant species, but most have only twig and leaf infections, not the rapid death observed in oaks.

Diatoms are stramenopiles with shells composed of two parts

Most **diatoms** are unicellular, although a few exist as colonies. The cell wall of each diatom consists of two shells that overlap where they fit together, much like a petri dish. Silica is deposited in the shell, and this glasslike material is laid down in intricate patterns (FIG. 26-10a). There are two basic groups of diatoms: those with radial symmetry (wheel shaped) and those with bilateral symmetry (boat shaped or needle shaped). Although some diatoms are part of the floating plankton, others live on rocks and sediments, where they move by gliding. This gliding movement is facilitated by the secretion of a slimy material from a small groove along the shell.

Diatoms most often reproduce asexually by mitosis. When a diatom divides, the two halves of its shell separate, and each becomes the larger half of a new diatom shell (FIG. 26-10b). Because the glass shell cannot grow, some diatom cells get progressively smaller with each succeeding generation. When a diatom reaches a fraction of its original size, sexual reproduction occurs, with the production of shell-less gametes. Sexual reproduction restores the diatom to its original size because the resulting *zygote*, a $2n$ cell that results from the fusion of n gametes, grows substantially before producing a new shell.

Diatoms are common in fresh water but are especially abundant in relatively cool ocean water. They are ecologically significant as major producers in aquatic ecosystems. At least one species is toxic and linked to shellfish poisonings, marine mammal strandings, and the deaths of sea lions along the central California coast.

When diatoms die, their shells trickle to the ocean floor and accumulate in layers that eventually become sedimentary rock. After millions of years, geologic upheaval has exposed some of these deposits on land. Called *diatomaceous earth*, these deposits are mined and used as filtering, insulating, and soundproofing materials. As a filtering agent, diatomaceous earth is used to refine raw sugar and process vegetable oils. Because of its abrasive properties, diatomaceous earth is a common ingredient in scouring powders and metal polishes; it is no longer added to most toothpastes because it is too abrasive for tooth enamel. The intricately detailed diatom shells are often used to test microscope resolution down to 1 μm .

Brown algae are multicellular stramenopiles

Brown algae are the largest and most complex of all algae commonly called seaweeds. All brown algae are multicellular and range in size from a few centimeters (about an inch) to 75 m (about 260 ft). Their body forms are branched filaments; tufts;

(a) False color SEM of a unicellular diatom. Note the striking shell that contains silica.

(b) Asexual reproduction in diatoms. After cell division, each new cell retains half of the original shell. The newly synthesized half of the shell always fits *inside* the original half. As a result, one of the new cells is slightly smaller than the other.

Figure 26-10 Diatoms

fleshy “ropes”; or thick, flattened branches. The largest brown algae, called *kelps*, are tough and leathery in appearance.

Many kelps have leaflike **blades** in which most photosynthesis occurs, stemlike **stipes**, and rootlike anchoring **holdfasts** (FIG. 26-11a). They often have gas-filled *bladders* that provide buoyancy. (The blades, stipes, and holdfasts of brown algae are not homologous to the leaves, stems, and roots of plants. Brown algae and plants arose from different unicellular ancestors, as shown in Figure 26-3.)

Reproduction is varied and complex in the brown algae. Their reproductive cells, both asexual zoospores and sexual gametes, are usually biflagellate. Most have a life cycle that exhibits **alternation of generations**, in which they spend part of their life as multicellular haploid organisms and part as multicellular diploid organisms (see Fig. 10-19c).

Brown algae are commercially important for several reasons. Their cell walls contain a polysaccharide called *algin* that is harvested from kelps such as *Macrocystis* and used as a thickening and stabilizing agent in ice cream, toothpaste, shaving cream, hair spray, and hand lotion. Brown algae are an important human food, particularly in eastern Asia, and they are rich sources of certain vitamins and minerals such as iodine.

(a) *Laminaria* is widely distributed on rocky coastlines of temperate and polar seas. It grows to 2 m (6.5 ft).

(b) A kelp (*Macrocystis pyrifera*) bed is ecologically important to aquatic organisms, including the sea lion shown here. Photographed off the coast of California.

Figure 26-11 Brown algae

Brown algae are common in cooler marine waters, especially along rocky coastlines, where they live mainly in the intertidal zone or relatively shallow offshore waters. Kelps form extensive underwater “forests,” or kelp beds (FIG. 26-11b). They are essential in that ecosystem as important food producers, and they provide habitat for many marine invertebrates, fishes, and mammals. The diversity of life supported by kelp beds rivals that found in coral reefs.

Most golden algae are unicellular biflagellates

Golden algae are found in both freshwater and marine environments. Most species are biflagellate, unicellular organisms, although some are colonial (FIG. 26-12a). A few of these stramenopiles lack flagella and are similar to amoebas in appearance except that golden algae contain chloroplasts. Tiny scales of either silica or calcium carbonate may cover the cells. Reproduction in golden algae is primarily asexual and involves the production of biflagellate, motile *zoospores*.

Most golden algae are photosynthetic, and the pigment composition

of golden algae gives them a golden or golden brown color. A few species ingest bacteria and other particles of food. Ecologically, golden algae are important producers in marine environments. They compose a significant portion of the ocean’s **nanoplankton**, extremely minute algae (2 to 10 μm) that are major producers because of their great abundance.

(a) LM of a colonial golden alga (*Synura*) found in freshwater lakes and ponds.

(b) SEM of a coccolithophorid (*Emiliania huxleyi*). Note the overlapping scales of calcium carbonate.

Figure 26-12 Golden algae

Classification of golden algae is controversial. Some biologists lump diatoms and golden algae in a single phylum, whereas others classify both groups as brown algae. At the other extreme, some biologists divide the golden algae into two phyla by placing many of the marine species, such as *coccolithophorids* (FIG. 26-12b), in a separate phylum.

CHECKPOINT 26.4

- What are the two main groups of chromalveolates? What are their distinguishing characters?
- Why do some biologists think that the apicomplexans descended from dinoflagellates?
- Which water mold has influenced human history? Explain your answer.
- What is the ecological significance of the diatoms? The brown algae?

26.5 Rhizarians

LEARNING OBJECTIVE

- 8 Describe the forams and actinopods, and explain why many biologists classify them in the rhizarian supergroup.

Rhizarians are a diverse supergroup of amoeboid cells that often have hard outer shells, called **tests**, through which cytoplasmic projections extend. The threadlike cytoplasmic projections suggest the name *rhizarian*, from the Greek *rhiza*, meaning “root.” Forams and actinopods are rhizarians, as are certain shell-less amoebas. Not all amoebas are rhizarians, however, and many amoeba species are more closely related

to other eukaryotic clades. Current molecular evidence indicates that the rhizarian supergroup is monophyletic.

Forams extend cytoplasmic projections that form a threadlike, interconnected net

Almost all **foraminiferans** (**forams**) are marine rhizarians that produce elaborate tests (FIG 26-13a). The ocean contains enormous numbers of forams, which secrete chalky, many-chambered tests with pores through which cytoplasmic projections are extended. (*Foraminifera* is derived from the Latin for “bearing openings.”) The cytoplasmic projections form a sticky, interconnected net that entangles prey. Many forams contain unicellular algal endosymbionts (green algae, red algae, or diatoms) that provide food by photosynthesis. Many foram species live on the ocean floor, but others are part of the plankton.

Dead forams settle on the bottom of the ocean, where their tests form a gray mud that is gradually transformed into chalk. With geologic uplifting, these chalk formations become part of the land, as in the White Cliffs of Dover in England. (The White Cliffs of Dover are the remains of a variety of carbonate organisms, not only forams.) Because foram tests often appear in rock layers covering oil deposits, geologists exploring for oil look for foram tests in rock strata. Forams are well preserved in the fossil record, and biologists use some as **index fossils**, markers to help identify ancient sedimentary rock layers (see Chapter 18).

Actinopods project slender axopods

Actinopods are mostly marine plankton rhizarians with long, filamentous cytoplasmic projections called **axopods** that protrude through pores in their shells (FIG. 26-13b). A cluster of

Figure 26-13 Rhizarians

microtubules strengthens each axopod. Unicellular algae and other prey become entangled in these axopods and are engulfed outside the main body of the actinopod; cytoplasmic streaming carries the prey inside the body. Many actinopods contain algal endosymbionts that provide them with the products of photosynthesis.

Some actinopods, called **radiolarians**, secrete elaborate, beautiful glassy shells made of silica. Radiolarians are an important constituent of marine plankton. When radiolarians and other actinopods die, their shells settle and become an ooze (sediment) that may be several meters thick on the ocean floor.

CHECKPOINT 26.5

- What character does the term rhizarian indicate about the forams and actinopods?

26.6 Archaeplastids

LEARNING OBJECTIVE

- Describe evidence supporting the hypothesis that red algae and green algae should be included in a monophyletic group with land plants.

In the classification scheme adopted in this text, the monophyletic group of **archaeplastids** includes red algae and green algae, which are discussed here, and land plants, which are in a separate kingdom (see Chapters 27 and 28). Biologists classify these groups together based on molecular data and on the presence of chloroplasts bounded by outer and inner membranes, suggesting that they developed directly from a

cyanobacterial endosymbiont. All photosynthetic protists other than archaeplastids have plastids surrounded by three or four membranes.

Red algae do not produce motile cells

The vast majority of **red algae** are multicellular organisms, although there are a few unicellular species. The multicellular body form of red algae commonly consists of complex, interwoven filaments that are delicate and feathery (**FIG. 26-14a**); a few red algae are flattened sheets of cells. Most multicellular red algae attach to rocks or other substrates by a basal hold-fast. Reproduction in the red algae is remarkably complex, with an alternation of sexual and asexual stages. No flagellate cells develop during the life cycle. Some unicellular red algae may exhibit unusual features. For example, in 2013 a team of scientists working in the United States, Germany, and France reported on the genome of a unicellular extremophilic red alga adapted to toxic hot sulfur springs. The genome includes at least 75 genes acquired from archaea and bacteria needed for this extreme lifestyle, providing a striking example of horizontal gene transfer involving a eukaryote. (See Chapter 23 and Figure 23-4 for a discussion of the evolutionary significance of horizontal gene transfer.)

Red algae primarily live in warm tropical ocean waters, although a few species occur in fresh water and in soil. Some red algae, known as *coralline algae*, incorporate calcium carbonate in their cell walls from the ocean water (**FIG. 26-14b**). The hard calcium carbonate may protect coralline algae from the rigors of wave action. These coralline red algae build “coral” reefs and are perhaps as crucial as coral animals in this process.

The cell walls of red algae often contain thick, sticky polysaccharides that have commercial value. For example, *agar* is a polysaccharide extracted from certain red algae used as a food thickener and culture medium, a substrate on which to grow microorganisms and propagate some plants, such as

(a) *Polysiphonia*, which is widely distributed throughout the world, has a highly branched body of interwoven filaments.

(b) *Bossiella* is a coralline red alga encrusted with calcium carbonate. It lives in the Pacific Ocean.

Figure 26-14 Red algae

(a) LM of *Volvox* colonies, each composed of thousands of cells. New colonies are inside the parental colonies, which eventually break apart.

(b) *Ulva*'s thin, sheetlike form suggests its common name, sea lettuce.

(c) *Chara*, a green alga commonly called a stonewort, is closely related to land plants. *Chara* is widely distributed in fresh water.

Figure 26-15 Green algae

orchids. Another polysaccharide extracted from red algae, *carrageenan*, is a food additive used to stabilize chocolate milk; it also provides a thick, creamy texture to ice cream and other soft processed foods. Carrageenan is also used to stabilize paints and cosmetics. Red algae are a source of vitamins (particularly A and C) and minerals, especially in Japan and other eastern Asian countries where people eat red algae fresh, dried, or toasted in such traditional foods as sushi and nori.

Green algae share many similarities with land plants

Green algae have pigments, energy reserve products, and cell walls that are chemically identical to those of land plants. Green algae are photosynthetic, with chloroplasts of a wide variety of shapes. Most green algae have cell walls with cellulose, although some lack walls. Because of these and other similarities, biologists generally accept that land plants arose from ancestral green algae (see Fig. 26-3). Based on recent molecular and ultrastructure data, some biologists classify this diverse group in the plant kingdom.

Green algae exhibit a variety of body types, from single cells to colonial forms, to coenocytic algae (multinucleate), to multicellular filaments and sheets (FIG. 26-15). The multicellular forms do not have cells differentiated into tissues, a characteristic that separates them from land plants. Most green algae have, or produce, flagellate cells during their life cycle, although a few are totally nonmotile.

Reproduction in the green algae is as varied as their body forms, with both sexual and asexual reproduction. Many green algae have life cycles with an alternation of multicellular haploid and multicellular diploid generations. Asexual reproduction is by mitosis and cell division in single cells or by fragmentation in multicellular forms. Many green algae produce spores asexually by mitosis; if these spores have flagella and are motile, they are called *zoospores* (FIG. 26-16). Sexual

reproduction in the green algae involves gamete formation in unicellular **gametangia** (sing., *gametangium*), reproductive structures in which gametes are produced. Green algae are found in both aquatic and terrestrial environments. Aquatic green algae primarily inhabit fresh water, although there are many marine species. Terrestrial green algae are restricted to damp soil, cracks in tree bark, and other moist places. Many green algae are symbionts with other organisms; some live as endosymbionts in body cells of invertebrates, and a few grow together with fungi as “compound organisms” called *lichens* (discussed in Chapter 29). Regardless of where they live, green algae are ecologically important as producers.

CHECKPOINT 26.6

- Why do many biologists classify red algae and green algae with land plants?

26.7 Unikonts

LEARNING OBJECTIVE

- 10** Briefly describe and compare the following unikonts: amoebas, plasmodial slime molds, cellular slime molds, and choanoflagellates.

Unikonts are a supergroup composed of certain amoebas, plasmodial slime molds, cellular slime molds, choanoflagellates, fungi (discussed in Chapter 29), and animals (discussed in Chapters 30 through 32). Unikonts share a single posterior flagellum in flagellate cells such as sperm and motile spores, although some extant organisms in this supergroup have lost the flagellum. Many unikonts also have a single centriole.

Figure 26-16 The life cycle of *Chlamydomonas*

Chlamydomonas is a unicellular, haploid green alga with two mating types, (+) and (-). The only diploid cell in the life cycle is the zygote.

Examine Figure 26-3 again and note that the unikonts are divided into two clades. One clade is the **opisthokonts**, which consist of fungi, choanoflagellates, and animals. You will learn more about the opisthokonts in Chapters 29 and 30.

Unikonts also have a **triple-gene fusion** that has major evolutionary significance. In a triple-gene fusion, three separate genes fused into a single unit early in the course of eukaryote evolution; the fused gene codes for a multi-enzyme protein. You may recall that Figure 26-3 showed all five supergroups branching from the same point, indicating that the branching order is unresolved. However, triple-gene fusion provides evidence of a bifurcation, or branch of the eukaryotes into two main clades, close to the root of the common ancestor of all eukaryotes (**FIG 26-17**). The two branches consist of (1) unikonts, which had a common ancestor with

a single posterior flagellum; and (2) all other eukaryotes, collectively called **bikonts**, which had a common ancestor with two flagella.

Amoebozoa are unikonts with lobose pseudopodia

Most **amoebozoa** produce temporary cytoplasmic projections called **pseudopodia** (sing., *pseudopodium*, meaning “false foot”) at some point in their life cycle. The pseudopodia of amoebozoa are **lobose**—that is, rounded and wide—as opposed to the slender cytoplasmic projections characteristic of rhizarians. Many biologists currently classify amoebas, plasmodial slime molds, and cellular slime molds as amoebozoa.

Key Experiment

How do we deduce details of eukaryote evolution near the root of the evolutionary tree?

HYPOTHESIS: Derived gene fusions, which have occurred rarely during the course of evolution, can provide insights into eukaryote evolutionary relationships.

EXPERIMENT: Alexandra Stechmann and Thomas Cavalier-Smith of Oxford University sequenced a double-gene fusion that codes for two enzymes: dihydrofolate reductase (DHFR) and thymidylate synthase (TS). In a second experiment, they sequenced a triple-fused gene involved in the enzymatic synthesis of pyrimidine nucleotides. They tested for the presence of these two gene fusions in various eukaryote groups as well as in bacteria and archaea.

RESULTS AND CONCLUSION: The double-gene fusion is present in all eukaryotes examined except for unikonts; bacteria and archaea also lack the double-gene fusion. The unikonts have the triple-gene fusion that is lacking in all other eukaryotes, bacteria, and archaea. These gene fusions suggest a fundamental division of eukaryotes into two main clades, the unikonts and all other eukaryotes, which are collectively called bikonts.

SOURCE: Stechmann, A., and T. Cavalier-Smith, "The Root of the Eukaryote Tree Pinpointed," *Current Biology*, Vol. 13 (2003): R665–R666.

Figure 26-17 Stechmann and Cavalier-Smith's research on evolution of the protists

CONNECT Are you a bikont or a unikont?

Amoebas move by forming pseudopodia Amoebas are unicellular amoebzoa found in soil, fresh water, the ocean, and other organisms (as parasites). Because of the extreme flexibility of their outer plasma membrane, many members of this group have an asymmetrical body form and continually change shape as they move. (The word *amoeba* derives from a Greek word meaning "change.") An amoeba moves by pushing out lobose pseudopodia from the surface of the cell. More cytoplasm flows into the pseudopodia, enlarging them until all the cytoplasm has entered and the organism as a whole has moved. Pseudopodia also capture and engulf food by surrounding and forming a vacuole around it (FIG. 26-18). Food particles are digested

when the food vacuole fuses with a lysosome containing digestive enzymes. Digested materials are absorbed from the food vacuole, which gradually shrinks as it empties. Amoebas reproduce asexually, splitting into two equal parts after mitotic division of the nucleus; sexual reproduction has not been observed.

Parasitic amoebas include *Entamoeba histolytica*, which causes *amoebic dysentery*, a serious human intestinal disease characterized by severe diarrhea, bloody stools, and ulcers in the intestinal wall. In especially severe cases the organism spreads from the large intestine and causes abscesses in the liver, lungs, or brain. *Entamoeba histolytica* is transmitted as cysts in contaminated drinking water. A *cyst* is a thick-walled, resistant, resting stage in the life cycle of some protists. Other amoebas, such as *Acanthamoeba*, are usually free-living but produce opportunistic infections such as eye infections in wearers of contact lenses.

Plasmodial slime molds feed as multinucleate plasmodia The feeding stage of a **plasmodial slime mold** is a **plasmodium**, a multinucleate mass of cytoplasm that can grow up to 30 cm (1 ft) in diameter (FIG. 26-19a). The slimy plasmodium streams over damp, decaying logs and leaf litter, often forming a network of channels that covers a large surface area. As it creeps along, it ingests bacteria, yeasts, spores, and decaying organic matter.

When the food supply dwindles or there is insufficient moisture, the plasmodium crawls to an exposed surface and starts reproducing. Stalked structures of intricate complexity and beauty usually form from the drying plasmodium (FIG. 26-19b). Within these structures, called **sporangia**, meiosis produces haploid spores that are extremely resistant to adverse environmental conditions.

When conditions become favorable, the spores germinate, and a haploid reproductive cell emerges from each. This haploid cell is either a biflagellate *swarm cell* or an amoeboid *myxamoeba*, depending on available moisture; flagellate cells form in wet conditions. Swarm cells and myxamoebas act as gametes, which fuse to form a zygote with a diploid nucleus. The resultant diploid nucleus divides many times by mitosis, but the cytoplasm does not divide, so the result is a multinucleate plasmodium.

The plasmodial slime mold *Physarum polycephalum* is a model organism that researchers use to study many fundamental biological processes, such as growth, cytoplasmic streaming, and the function of the cytoskeleton.

Cellular slime molds feed as individual amoeboid cells The **cellular slime molds** are amoebzoa with close affinities to amoebas and plasmodial slime molds. During its feeding stage, each cellular slime mold is an individual amoeboid cell that behaves as a separate, solitary organism (FIG. 26-20). Each cell creeps over rotting logs and soil or swims in fresh water, ingesting bacteria and other particles of food as it goes. Each amoeboid cell has a haploid nucleus and reproduces by mitosis, as a true amoeba does.

When moisture or food becomes inadequate, certain cells send out a chemical signal, cyclic adenosine monophosphate (cAMP; see Fig. 3-26), that causes them to aggregate by the hundreds or thousands. During this stage the cells creep about

Figure 26-18 Amoeba

LM of a giant amoeba (*Chaos carolinense*). This unicellular protist, which moves and feeds by pseudopodia, is surrounding and ingesting a colonial green alga. *Chaos* amoebas are generally scavengers that feed on debris in freshwater habitats, but they ingest living organisms when the opportunity arises.

for short distances as a single multicellular aggregate, or slug. Each cell of the slug retains its plasma membrane and individual identity. Eventually, the slug settles and reorganizes, forming a stalked fruiting body containing spores. After being released each spore opens, and a single haploid amoeboid cell—the feeding stage—emerges. The spore-forming reproductive cycle is asexual, although sexual reproduction is observed occasionally. The life cycles of most cellular slime molds lack a flagellate stage.

The cellular slime mold *Dictyostelium discoideum* is a model organism for the study of cell differentiation, cell communication, and cell motility and adhesion. Its biology has been studied intensively, particularly as it relates to **cell signaling** molecules, such as cAMP, which are found in many organisms in addition to the cellular slime molds (see Chapter 6).

Choanoflagellates are opisthokonts closely related to animals

Choanoflagellates are collared flagellates in the opisthokont clade, which also includes fungi and animals. These small, inconspicuous unikonts are found globally in both freshwater and marine environments. Choanoflagellates include both free-swimming and **sessile** species that are permanently attached by a thin stalk to bacteria-rich debris. Their single flagellum is surrounded at its base by a delicate collar of microvilli that trap food (FIG. 26-21).

Choanoflagellates are of special interest because of their striking resemblance to collar cells in sponges (see Fig. 31-1b). Other animal phyla, such as cnidarians, flatworms, and echinoderms, also contain choanoflagellate-like cells, but no other group of protists has been observed to possess these cells. Evidence supporting the close relationship

(a) The brightly pigmented plasmodium, shown on a dead log, feeds on bacteria and other microorganisms.

(b) The reproductive structures are sporangia on stalks.

Figure 26-19 The plasmodial slime mold *Physarum polycephalum*

Figure 26-20 The cellular slime mold *Dictyostelium discoideum*

Slime mold amoebas ingest food, grow, and reproduce by cell division. After their food is depleted, hundreds of amoeboid cells stream together (*inset in upper right*) and form a migrating slug-like aggregate (*inset in lower left*). When it stops migrating, the aggregate forms a fruiting body on a stalk (*inset in upper left*). The fruiting body releases spores, each of which opens in a favorable environment to liberate an amoeboid cell.

between choanoflagellates and animals includes comparative DNA sequence data of mitochondrial and nuclear genes. Given the similarities in structure and molecular genomics that has accumulated in recent years, many biologists hypothesize that choanoflagellates are the closest living non-animal relative of animals. Thus, living choanoflagellates and animals probably share a common choanoflagellate-like ancestor.

CHECKPOINT 26.7

- What features distinguish the amoebozoa from the rhizarians?
- **CONNECT** Which group of unikonts is structurally and genetically most similar to animals?

Figure 26-21 Choanoflagellates

Choanoflagellates are free-living flagellates that obtain food by waving their flagella, causing water currents to carry bacteria and other small particles of food into the collar of microvilli. A colonial form is shown. Each cell is 5 to 10 μm long, not including the flagellum.

Summary: Focus on Learning Objectives

26.1 Diversity in the Protists (page 540)

- 1 Discuss in general terms the diversity inherent in protists, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.
 - Protists have various means of locomotion, including **pseudopodia**, **flagella**, and **cilia**; a few are nonmotile.

- Protists obtain their nutrients autotrophically or heterotrophically. Protists are free-living or symbiotic, with symbiotic relationships ranging from **mutualism** to **parasitism**.
- Most protists live in the ocean or in freshwater ponds, lakes, and streams. Parasitic protists live in the body fluids or cells of their hosts.
- Many protists reproduce both sexually and asexually; others reproduce only asexually.

26.2 How Did Eukaryotes Evolve? (page 541)

- 2 Discuss the hypothesis of serial endosymbiosis and briefly explain some of the evidence that supports it.
 - According to the hypothesis of **serial endosymbiosis**, mitochondria and chloroplasts arose from symbiotic relationships between larger cells and the smaller bacteria that were incorporated and lived within them.
 - Chloroplasts of red algae, green algae, and plants probably arose in a single primary endosymbiotic event in which a cyanobacterium was incorporated into a cell. Multiple secondary endosymbioses led to chloroplasts in euglenoids, dinoflagellates, diatoms, golden algae, and brown algae and to the nonfunctional chloroplasts in apicomplexans.
- 3 Describe the kinds of data biologists use to classify eukaryotes.
 - Relationships among protists are determined largely by **ultrastructure**, which is the fine details of cell structure revealed by electron microscopy, and by comparative molecular data. Biologists have compared nuclear genes, many of which code for proteins, in different protist taxa.

26.3 Excavates (page 544)

- 4 Summarize the basic features of excavates and distinguish among diplomonads, parabasalids, and euglenoids.
 - **Excavates** are a diverse group of unicellular protists with flagella, an excavated oral groove, and atypical, greatly modified mitochondria. The inclusion of diplomonads, parabasalids, and euglenoids in the excavate superfamily is controversial.
 - **Diplomonads** are excavates with one or two nuclei, no functional mitochondria, no Golgi complex, and up to eight flagella.

- **Parabasilids** are anaerobic, flagellated excavates that often live in animals. Trichonymphs and trichomonads are examples of parabasilids.
- **Euglenoids** are unicellular and flagellate. Some euglenoids are photosynthetic.

26.4 Chromalveolates (page 546)

- 5 Contrast the two main groups of chromalveolates: alveolates and stramenopiles.
 - **Chromalveolates** probably originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga. Some DNA sequence data suggest that the chromalveolates are not monophyletic.
 - **Alveolates** have similar ribosomal DNA sequences and alveoli, flattened vesicles located just inside the plasma membrane. Most **stramenopiles** have motile cells with two flagella, one of which has tiny hairlike projections off the shaft.
- 6 Distinguish among the alveolates: dinoflagellates, apicomplexans, and ciliates.
 - **Dinoflagellates** are mostly unicellular, biflagellate, photosynthetic alveolates of great ecological importance as producers in marine ecosystems. Their **alveoli**, flattened vesicles under the plasma membrane, often contain cellulose plates impregnated with silicates. Some dinoflagellates produce toxic blooms known as **red tides**.
 - **Apicomplexans** are parasites that produce **sporozoites** and are nonmotile. An apical complex of microtubules attaches the apicomplexan to its host cell. The apicomplexan *Plasmodium* causes malaria.
 - **Ciliates** are alveolates that move by hairlike cilia, have **miconuclei** (for sexual reproduction) and **macronuclei** (for controlling cell metabolism and growth), and undergo a sexual process called **conjugation**.
- 7 Distinguish among the stramenopiles: water molds, diatoms, golden algae, and brown algae.
 - **Water molds** have a coenocytic **mycelium**. They reproduce asexually by forming biflagellate **zoospores** and sexually by forming **oospores**.
 - **Diatoms** are mostly unicellular, with shells containing silica. Some diatoms are part of floating **plankton**, and others live on rocks and sediments where they move by gliding.
 - **Brown algae** are multicellular stramenopiles that are ecologically important in cooler ocean waters. The largest brown algae (kelps) possess leaflike **blades**, stemlike **stipes**, anchoring **holdfasts**, and gas-filled bladders for buoyancy.
 - **Golden algae** are mostly unicellular, biflagellate freshwater and marine stramenopiles that are of ecological importance as a component of the ocean's extremely minute **nanoplankton**.

26.5 Rhizarians (page 553)

- 8 Describe the forams and actinopods, and explain why many biologists classify them in the rhizarian supergroup.

- **Rhizarians** are amoeboid cells that often have hard outer shells, called **tests**, through which cytoplasmic projections extend; molecular evidence indicates that this group is monophyletic.
- **Forams** secrete many-chambered tests with pores through which cytoplasmic projections extend to move and obtain food.
- **Actinopods** are mostly marine plankton that obtain food by means of **axopods**, slender cytoplasmic projections that extend through pores in their shells.

26.6 Archaeplastids (page 554)

9 Describe evidence supporting the hypothesis that red algae and green algae should be included in a monophyletic group with land plants.

- Red algae, green algae, and land plants, collectively called **archaeplastids**, are considered a monophyletic group based on molecular data and on the presence of chloroplasts bounded by outer and inner membranes.
- **Red algae**, which are mostly multicellular seaweeds, are ecologically important in warm tropical ocean waters.

- **Green algae** exhibit a wide diversity in size, structural complexity, and reproduction. Botanists hypothesize that ancestral green algae gave rise to land plants.

26.7 Unikonts (page 555)

10 Briefly describe and compare the following unikonts: amoebas, plasmodial slime molds, cellular slime molds, and choanoflagellates.

- **Unikonts** have a single posterior flagellum in flagellate cells.
- **Amoebas** move and obtain food using cytoplasmic extensions called pseudopodia.
- The feeding stage of **plasmodial slime molds** is a multinucleate **plasmodium**. Reproduction is by haploid spores produced within **sporangia**.
- **Cellular slime molds** feed as individual amoeboid cells. They reproduce by aggregating into an aggregate (slug) and then forming asexual spores.
- **Choanoflagellates** are unikonts that are probably the closest living nonanimal relative of animals. A collar of microvilli surrounds their single flagellum at its base. Choanoflagellates are included with animals in the **opisthokont** clade, which also includes fungi.

Test Your Understanding

Know and Comprehend

- Which of the following is *not* true of the protists? (a) they are unicellular, colonial, coenocytic, or simple multicellular organisms (b) their cilia and flagella have a 9 + 2 arrangement of microtubules (c) they are prokaryotic, as bacteria and archaea are (d) some are free-living, and some are endosymbionts (e) most are aquatic and live in the ocean or in freshwater ponds
- Molecular evidence supports the view that all plastids evolved from an ancient (a) cyanobacterium (b) archaean (c) diplomonad (d) apicomplexan (e) unikont
- Forams (a) are endosymbionts that live in many marine invertebrates (b) were responsible for the Irish potato famine in the 19th century (c) secrete many-chambered tests with pores through which cytoplasmic extensions project (d) have numerous axopods that may aid in trapping and holding prey (e) have numerous cilia to direct food into the oral groove
- Paramecium* and other ciliates often display a sexual phenomenon called (a) oogamy (b) conjugation (c) serial endosymbiosis (d) red tide (e) alternation of generations
- Parasitic alveolates that form spores at some stage in their life belong to which group? (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
- Malaria (a) is transmitted by the bite of a female tsetse fly (b) is caused by a parasitic flagellate, *Giardia intestinalis* (c) is a serious form of amoebic dysentery caused by *Entamoeba histolytica* (d) is caused by an apicomplexan that spends part of its life cycle in the *Anopheles* mosquito and part in humans (e) is transmitted when people drink water tainted by a red tide
- Photosynthetic protists with shells composed of two halves that fit together like a petri dish are (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) forams
- The pigments, energy reserve products, and cell walls found in land plants are also characteristic of (a) green algae (b) brown algae (c) golden algae (d) diatoms (e) euglenoids and diatoms
- Kelps are _____ with multicellular bodies differentiated into blades, stipes, holdfasts, and gas-filled floats. (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) red algae
- Cellular slime molds (a) include *Physarum* and *Phytophthora* (b) are more closely related to bacteria than are any other protists (c) are responsible for late blight of potatoes, which led to starvation in Ireland in the 1840s (d) have double-gene fusion (e) form a slug when cells aggregate in response to cyclic AMP
- Water molds reproduce asexually by forming _____ and sexually by forming _____. (a) oospores; holdfasts (b) zoospores; zooxanthellae (c) zoospores; oospores (d) holdfasts; oospores (e) oospores; zoospores

Apply and Analyze

- VISUALIZE** Draw simple sketches of a *Euglena* and a *Paramecium*. Choose the appropriate structures for each organism from the following list and label them in your drawings: flagellum, cilia, chloroplast, mitochondrion, nucleus, macronucleus, micronucleus, contractile vacuole, pellicle, food vacuole.

Evaluate and Synthesize

13. **EVOLUTION LINK** Why are the protists considered paraphyletic? Use Figure 26-3 to help explain your answer.
14. **INTERPRET DATA** In the corresponding darkfield LM of unicellular choanoflagellates, actin has been stained *red*, tubulin *green*, and DNA *blue*. Identify the cell parts that contain each of these chemical materials.

Nicole King Lab, University of California, Berkeley

15. **SCIENCE, TECHNOLOGY, AND SOCIETY** Use examples associated with the malaria parasite, *Plasmodium*, to illustrate why an understanding of evolution is indispensable to modern medical research. (*Hint*: Be sure to include serial endosymbiosis and drug resistance in your answer.)

For access to MindTap and additional study materials visit www.cengagebrain.com.

27 Seedless Plants

About 445 million years ago (mya), planet Earth would have seemed an inhospitable place because even though life abounded in the ocean, it did not yet exist in abundance on land. Occasionally, perhaps, an animal would crawl out of the water onto land, but it never stayed there permanently because there was little to eat on land: not a single blade of grass, no fruit, and no seeds.

During the next 30 million years, a time corresponding roughly to the Silurian period in geologic time (see Table 21-1), plants appeared in abundance and colonized the land. Where did they come from? Although plants living today exhibit great diversity in size, form, and habitat (see photograph), biologists hypothesize that they all evolved from a common ancestor that was an ancient green alga.

Modern green algae share many biochemical and metabolic traits with modern plants. Both green algae and plants contain the same photosynthetic pigments: chlorophylls *a* and *b* and carotenoids, including xanthophylls (yellow pigments) and carotenes (orange pigments). Both store excess carbohydrates as starch and have cellulose as a major component of their cell walls. In addition, plants and some green algae share certain details of cell division, including formation of a cell plate during cytokinesis (see Chapter 10).

What exactly is a plant? A **plant** is a complex multicellular eukaryote that has cellulose cell walls, chlorophylls *a* and *b* in plastids, and starch as a storage product and that may have cells with two anterior flagella. In addition, all plants develop from multicellular *embryos* that are enclosed in maternal tissues; this last character is one that distinguishes plants from green algae. Many botanists refer to land plants as *embryophytes* because of this character.

Plants range in size from minute, almost microscopic duckweeds and water-meal to massive giant sequoias, some of the largest organisms that have ever lived. Plants include hundreds of thousands of species that live in varied habitats, from frozen arctic tundra to lush tropical rain forests to harsh deserts to moist stream banks.

KEY CONCEPTS

- 27.1** Adaptations of land plants include a waxy cuticle to prevent water loss; multicellular gametangia; stomata; and for most plants, vascular tissues containing lignin. Plants undergo an alternation of generations between multicellular gametophyte and sporophyte generations.
- 27.2** Mosses and other bryophytes lack vascular tissues and do not form true roots, stems, or leaves.
- 27.3** In club mosses and ferns, lignin-hardened vascular tissues that transport water and dissolved substances throughout the plant body have evolved.

27.1 Adaptations of Plants to Life on Land

LEARNING OBJECTIVES

- 1 Discuss some environmental challenges of living on land and describe how several plant adaptations meet these challenges.
- 2 Name the green algal group from which plants are hypothesized to have descended and describe supporting evidence.

How were plants modified during the transition from life in the water to life on land? What are some features of plants that have let them colonize so many types of environments? One important difference between plants and algae is that a waxy **cuticle** covers the aerial portion of a plant. Essential for existence on land, the cuticle helps prevent desiccation, or drying out, of plant tissues by evaporation. Plants that are adapted to moister habitats may have a very thin layer of wax, whereas those adapted to drier environments often have a thick, crusty cuticle. (Many desert plants also have a reduced surface area, particularly of leaves, which minimizes water loss.)

Plants obtain the carbon they need for photosynthesis from the atmosphere as carbon dioxide (CO_2). To be fixed into organic molecules such as sugar, CO_2 must first diffuse into the chloroplasts that are inside green plant cells. Because a waxy cuticle covers the external surfaces of leaves and stems, however, gas exchange through the cuticle between the atmosphere and the interior of cells is negligible. Tiny pores called **stomata** (sing., *stoma*), which dot the surfaces of leaves and stems of almost all plants, facilitate gas exchange.

The sex organs, or **gametangia** (sing., *gametangium*), of most plants are multicellular, whereas the gametangia of algae are unicellular (FIG. 27-1). Each plant gametangium has a layer of sterile (nonreproductive) cells that surrounds and protects the delicate gametes (eggs and sperm cells). In plants the fertilized egg develops into a multicellular **embryo** (young plant) within the female gametangium. Thus, the embryo is protected during its development. In algae the fertilized egg develops away from its gametangium; in some algae the gametes are released before fertilization, whereas in others the fertilized egg is released.

The plant life cycle alternates between haploid and diploid generations

Plants have a clearly defined **alternation of generations** in which they spend part of their lives in a multicellular haploid stage and part in a multicellular diploid stage (FIG. 27-2).¹ The haploid portion of the life cycle is called the **gametophyte generation** because it gives rise to haploid gametes by mitosis. When two gametes fuse, the

diploid portion of the life cycle, called the **sporophyte generation**, begins. The sporophyte generation produces haploid spores by the process of meiosis; these spores represent the first stage in the gametophyte generation.

Let us examine alternation of generations more closely. The haploid gametophytes produce male gametangia, known as **antheridia** (sing., *antheridium*), in which sperm cells form (FIG. 27-3a). Gametophytes also produce female gametangia, known as **archegonia** (sing., *archegonium*), each bearing a single egg (FIG. 27-3b). Sperm cells reach the female gametangium in a variety of ways, and one sperm cell fertilizes the egg to form a **zygote**, or fertilized egg.

The diploid zygote is the first stage in the sporophyte generation. The zygote divides by mitosis and develops into a multicellular embryo, the young sporophyte plant. Embryo development takes place within the archegonium; thus, the embryo is protected as it develops. Eventually, the embryo grows into a mature sporophyte plant. The mature sporophyte has special cells called **sporogenous cells** (spore-producing cells, also called *spore mother cells*) that divide by meiosis to form haploid **spores**.

fertilization of egg by sperm cell → zygote → embryo →
mature sporophyte plant → sporogenous cells → meiosis
→ spores

All plants produce spores by meiosis, in contrast with algae and fungi, which may produce spores by meiosis or mitosis. The spores represent the first stage in the gametophyte generation. Each spore divides by mitosis to produce a multicellular gametophyte, and the cycle continues. Plants therefore alternate between a haploid gametophyte generation and a diploid sporophyte generation.

spores → mature gametophyte plants → archegonia → eggs
antheridia → sperm cells

Figure 27-1 Generalized reproductive structures of algae and plants
(a, b) In algae, gametangia are generally unicellular. When the gametes are released, only the wall of the original cell remains. (c, d) In plants, the gametangia are multicellular, but only the inner cells become gametes. The gametes are surrounded by a protective layer of sterile (nonreproductive) cells.

¹ For convenience, we limit our discussion to plants that are not polyploid, although polyploidy is very common in land plants. We therefore use the terms *diploid* and $2n$ (and *haploid* and n) interchangeably, but these terms are not actually synonymous.

Key Point

Plants have an alternation of generations, spending part of the cycle in a haploid gametophyte stage and part in a diploid sporophyte stage.

Figure 27-2 The basic plant life cycle

Depending on the plant group, the haploid or the diploid stage may be greatly enlarged or reduced; as you will learn, this fact has evolutionary significance.

CONNECT Do diploid cells undergo mitosis in this life cycle? haploid cells?

Four major groups of plants exist today

Structural and molecular data indicate that land plants probably descended from a group of green algae called **charophytes** or **stoneworts** (see Figure 26-15c, which shows a charophyte). Recall from Chapter 26 that red algae, green algae, and land

plants are collectively classified as **archaeplastids**. Molecular comparisons, particularly of DNA and RNA sequences, provide compelling evidence that green algae are closely allied to plants (**FIG. 27-4**). These comparisons among plants and various green algae include sequences of chloroplast DNA, certain nuclear genes, and ribosomal RNA. In each case, the closest match

(a) Each antheridium, the male gametangium, produces numerous sperm cells.

(b) Each archegonium, the female gametangium, produces a single egg.

Figure 27-3 Plant gametangia

Shown are generalized moss gametangia.

Figure 27-4 Evolution of land plants

Cladograms such as this one represent an emerging consensus that is open to change as new discoveries are made.

occurs between charophytes and plants, indicating that modern charophytes and plants probably share a recent common ancestor.

Plants consist of four major groups: bryophytes; seedless vascular plants; and two groups of seeded vascular plants, the gymnosperms and angiosperms (flowering plants). Their relationships are illustrated in **FIGURE 27-5**; see also **TABLE 27-1**, which is an overview of the ten extant (living) plant phyla.

The mosses and other bryophytes are small nonvascular plants that lack a specialized vascular, or conducting, system to transport nutrients, water, and essential minerals (inorganic nutrients) throughout the plant body. In the absence of such a system, bryophytes rely on diffusion and osmosis to obtain needed materials. This reliance means that bryophytes are restricted in size; if they were much larger, some of their cells could not obtain enough necessary materials. Bryophytes do not form seeds, the reproductive structures discussed in Chapter 28. Bryophytes reproduce and disperse primarily via haploid spores. Recent molecular and fossil evidence, discussed later in this chapter, suggests that bryophytes may have been the earliest plants to colonize land.

The other three groups of plants—seedless vascular plants, gymnosperms, and flowering plants—have vascular tissues and are thus known as vascular plants. The two vascular tissues are **xylem**, for conducting water and dissolved minerals, and **phloem**, for conducting dissolved organic molecules such as sugar. A key step in the evolution of vascular plants was the ability to produce **lignin**, a strengthening polymer in the walls of cells that function for support and conduction (see Chapter 33 for a discussion of plant cell wall chemistry, including lignin). The stiffening property of lignin enabled plants to grow tall, which let them maximize light interception. The successful occupation of the land by plants, in turn, made the evolution of terrestrial animals possible by providing them with both habitat and food.

Club mosses and ferns (which include whisk ferns and horsetails) are seedless vascular plants that, like the bryophytes, reproduce and disperse primarily via spores. Seedless vascular plants arose and diversified during the Silurian and Devonian periods of the Paleozoic era, between 444 mya and 359 mya. Club mosses and ferns extend back more than 420 million years and were of considerable importance as Earth's dominant

Key Point

Based on recent evidence, scientists are beginning to reach a consensus about the evolutionary relationships among living plants.

Figure 27-5 Plant evolution

The four major groups of plants are bryophytes, seedless vascular plants, and two groups of seed plants: gymnosperms and angiosperms. The seed plants are covered in Chapter 28.

CONNECT How does the cladogram relate to many botanists referring to land plants as embryophytes?

plants in past ages. Fossil evidence indicates that many species of these plants were the size of immense trees. Most living representatives of club mosses and ferns are small.

The gymnosperms are vascular plants that reproduce by forming seeds. Gymnosperms produce seeds borne exposed (unprotected) on a stem or in a cone. Plants with seeds as their primary means of reproduction and dispersal first appeared about 359 mya, at the end of the Devonian period. These early seed plants diversified into many varied species of gymnosperms.

The most recent plant group to appear is the flowering plants, or angiosperms, which arose during the early Cretaceous period of the Mesozoic era, about 130 mya. Like gymnosperms, flowering plants reproduce by forming seeds. Flowering plants, however, produce seeds enclosed within a fruit.

CHECKPOINT 27.1

- What are the most important environmental challenges that plants face living on land?
- What adaptations do plants have to meet these environmental challenges?
- What types of evidence support the hypothesis that land plants descended from the group of green algae known as charophytes?
- **VISUALIZE** Draw a simple diagram illustrating alternation of generations in plants, including the sporophyte and gametophyte generations, spores, gametes (eggs and sperm), meiosis, and fertilization. Be sure to indicate whether each generation or kind of cell is haploid or diploid.

Table 27-1 Ten Extant Plant Phyla

	NONVASCULAR PLANTS WITH A DOMINANT GAMETOPHYTE GENERATION (BRYOPHYTES) Phylum Hepatophyta (liverworts) Phylum Bryophyta (mosses) Phylum Anthocerophyta (hornworts)
	VASCULAR PLANTS WITH A DOMINANT SPOROPHYTE GENERATION Seedless plants Phylum Lycopodiophyta (club mosses) Phylum Pteridophyta (ferns and their allies, the whisk ferns and horsetails)
	Seed plants Plants with naked seeds (gymnosperms) Phylum Coniferophyta (conifers) Phylum Cycadophyta (cycads) Phylum Ginkgophyta (ginkgoes) Phylum Gnetophyta (gnetophytes)
	Seeds enclosed within a fruit (angiosperms) Phylum Anthophyta (angiosperms or flowering plants) Class Eudicotyledones (eudicots) Class Monocotyledones (monocots)

27.2 Bryophytes

LEARNING OBJECTIVES

- Summarize the features that distinguish bryophytes from other plants.
- Name and briefly describe the three phyla of bryophytes.
- Describe the life cycle of mosses and compare their gametophyte and sporophyte generations.

The **bryophytes** (from the Greek words meaning “moss plant”) consist of about 16,000 species of mosses, liverworts, and hornworts; bryophytes are the only living nonvascular plants

(**TABLE 27-2**). Because they have no means for extensive internal transport of water, sugar, and essential minerals, bryophytes are typically small. They generally require a moist environment for active growth and reproduction, but some bryophytes tolerate dry areas.

The bryophytes are divided into three distinct phyla: mosses (phylum Bryophyta), liverworts (phylum Hepatophyta), and hornworts (phylum Anthocerophyta). These three groups differ in many ways and may or may not be closely related. They are usually studied together because they lack vascular tissues and have similar life cycles.

Moss gametophytes are differentiated into “leaves” and “stems”

Mosses (phylum Bryophyta), which include about 9900 species, usually live in dense colonies or beds (**FIG. 27-6**). Each individual gametophyte plant has tiny, hairlike absorptive structures called *rhizoids* and an upright, stemlike structure that bears leaflike blades, each normally consisting of a single layer of undifferentiated cells except at the midrib. Because mosses lack vascular tissues, they do not have true roots, stems, or leaves; the moss structures are not homologous to roots, stems, or leaves in vascular plants. Some moss species have water-conducting cells and sugar-conducting cells, although these cells are not lignified, nor are they as specialized or effective as the conducting cells of vascular plants.

Alternation of generations is clearly defined in the life cycle of mosses (**FIG. 27-7**). The green moss gametophyte often bears its gametangia at the top of the plant. Many moss species have separate sexes: male plants that bear antheridia and female plants that bear archegonia. Other mosses produce antheridia and archegonia on the same plant.

Fertilization occurs when one of the sperm cells fuses with the egg within the archegonium. Sperm cells, which have flagella, are transported from antheridium to archegonium by flowing water, such as splashing rain droplets. A raindrop lands on the top of a male gametophyte, and sperm cells are released into it from the antheridia. Another raindrop landing on the male plant may splash the sperm-laden droplet into the air and onto the top of a nearby female plant. Alternatively, arthropods such as insects and mites may touch the

Table 27-2 A Comparison of Major Groups of Seedless Plants

Plant Group	Dominant Stage of Life Cycle	Representative Genera
NONVASCULAR; REPRODUCE BY SPORES (BRYOPHYTES)		
Liverworts (phylum Hepatophyta)	Gametophyte: thalloid or leafy plant	<i>Marchantia</i>
Mosses (phylum Bryophyta)	Gametophyte: leafy plant	<i>Polytrichum</i> , <i>Sphagnum</i> , <i>Physcomitrella</i>

Figure 27-6 Bryophytes: mosses

sperm-laden fluid and inadvertently carry it for considerable distances. Once in a film of water on the female moss, a sperm cell swims into the archegonium, which secretes chemicals to attract and guide the sperm cells, and fuses with the egg.

The diploid zygote, formed by fertilization, grows by mitosis into a multicellular embryo that develops into a mature moss sporophyte. This sporophyte grows out of the top of the female gametophyte and remains attached and nutritionally dependent on the gametophyte throughout its existence (see Fig. 27-6b). Initially green and photosynthetic, the sporophyte becomes golden brown at maturity. It consists of three main parts: a *foot*, which anchors the sporophyte to the gametophyte and absorbs minerals and nutrients from it; a *seta*, or stalk; and a *capsule*, which contains sporogenous cells (spore mother cells). The capsule of some species is covered by a caplike structure, the *calyptra*, which is derived from the archegonium.

The sporogenous cells undergo meiosis to form haploid spores. When the spores are mature, the capsule opens and releases them, and they are then transported by wind or rain. If a moss spore lands in a suitable spot, it germinates and grows into a filament of cells called a **protonema**. The protonema, which superficially resembles a filamentous green alga, forms buds, each of which grows into a green gametophyte, and the life cycle continues.

Biologists consider the haploid gametophyte generation the dominant generation in mosses because it lives independently of the diploid sporophyte. In contrast, the moss sporophyte is attached to and nutritionally dependent on the gametophyte.

Mosses make up an inconspicuous but significant part of their environment. They play an important role in forming soil. Mosses, which form mats that cover the rock, eventually die, forming a thin layer of organic matter in which grasses and other plants can grow. Because they grow tightly packed in dense colonies, mosses hold soil in place and help prevent erosion. At the same time, they retain moisture that they and other organisms need. Waxwings and other birds use moss, along with twigs and grass, as nesting material.

Commercially, the most important mosses are the peat mosses in the genus *Sphagnum*. One of the distinctive features of *Sphagnum* “leaves” is the presence of many large, empty cells that absorb and hold water. This feature makes peat moss a useful packing material for shipping live plants as well as a good soil conditioner. Added to sandy soils, for example, peat moss helps absorb and retain moisture.

The acidic and anaerobic conditions of a peat bog retard the growth of bacterial and fungal decomposers. As a result, dead peat mosses accumulate as thick deposits—some several meters in depth—under the growing mat of living peat mosses.

The dominant phase in the life cycle of mosses, like that of other bryophytes, is the gametophyte.

Figure 27-7 The life cycle of mosses

The gametophyte generation is dominant in the moss life cycle. After sexual reproduction, the sporophyte grows out of the gametophyte.

VISUALIZE Sketch an embryo developing in an archegonium. Indicate to what generation each belongs and whether the tissue is haploid or diploid.

Over time, the organic material compresses to form *peat*. In some countries, such as Ireland and Scotland, people cut out blocks of peat that has accumulated for hundreds of years in peat bogs, dry them, and burn them for fuel. Occasionally, the remains of well-preserved humans have been uncovered during the excavations of old peat bogs in Ireland and other parts of Europe (**FIG. 27-8**).

The name *moss* is often misused to refer to plants that are not truly mosses. For example, reindeer “moss”

Figure 27-8 Preserved human remains in a peat bog in Denmark

The clothing and features of the Tollund man, estimated to be about two thousand years old, are remarkably well preserved because the bog’s acidic conditions inhibited decay.

is a lichen that is a dominant form of vegetation in the arctic tundra, Spanish “moss” is a flowering plant, and club “moss” (discussed later in this chapter) is a relative of ferns.

Liverwort gametophytes are either thalloid or leafy

Liverworts (phylum Hepatophyta) consist of about 6000 species of nonvascular plants with a dominant gametophyte generation,

but the gametophytes of some liverworts are quite different from those of mosses. Their body form is often a flattened, lobed structure called a **thallus** (pl., *thalli*) that is not differentiated into leaves, stems, or roots. The common liverwort, *Marchantia polymorpha*, is thalloid (FIGS. 27-9a and b). Liverworts are so named because the lobes of their thalli superficially resemble the lobes of the human liver; *wort* is derived from the Old English word *wyrt*, meaning “plant.” On the underside of the liverwort thallus are hairlike rhizoids that anchor the plant to the soil.

Figure 27-9 Bryophytes: liverworts

Other liverworts, known as *leafy liverworts*, superficially resemble mosses, with leaflike blades, “stems,” and rhizoids rather than a lobed thallus (FIG. 27-9c). As in the mosses, leafy liverwort “leaves” consist of a single layer of undifferentiated cells. Like other bryophytes, liverworts are small, generally inconspicuous plants that are largely restricted to damp environments. Unlike mosses, hornworts, and other plants, liverworts lack stomata, although some liverworts have surface pores thought to be analogous to stomata.

Liverworts reproduce both sexually and asexually (see Figs. 27-9a and b). Their sexual reproduction involves production of archegonia and antheridia on the haploid gametophyte. In some liverworts these gametangia are borne on stalked structures called *archegoniophores*, which bear archegonia, and *antheridiophores*, which bear antheridia. Their life cycle is basically the same as that of mosses, although some of the structures look quite different. Splashing raindrops transport sperm cells to the archegonia, where fertilization takes place. The resulting zygote develops into a multicellular embryo that becomes a mature sporophyte. The liverwort sporophyte is attached to the gametophyte, as in mosses. Sporogenous cells in the capsule of the sporophyte undergo meiosis, producing haploid spores. Each spore has the potential to develop into a green gametophyte, and the cycle continues.

Some liverworts reproduce asexually by forming tiny balls of tissue called **gemmae** (sing., *gemma*), which are borne in a saucer-shaped structure, the gemmae cup, directly on the liverwort thallus (see Fig. 27-9a). Splashing raindrops and small animals help disperse gemmae. When a gemma lands in a suitable place, it grows into a new liverwort thallus. Liverworts may also reproduce asexually by thallus branching and growth. The individual thallus lobes elongate, and each becomes a separate plant when the older part of the thallus that originally connected the individual lobes dies.

Hornwort gametophytes are inconspicuous thalloid plants

Hornworts (phylum Anthocerophyta) are a small group of about 100 species of bryophytes whose gametophytes superficially resemble those of the thalloid liverworts. Hornworts live in disturbed habitats such as fallow fields and roadsides.

Hornworts may or may not be closely related to other bryophytes. For example, their cell structure, particularly the presence of a single large chloroplast in each cell, resembles certain algal cells more than plant cells. In contrast, mosses, liverworts, and other plants have many disc-shaped chloroplasts per cell.

In the common hornwort (*Anthoceros natans*), archegonia and antheridia are embedded in the gametophyte thallus rather than on archegoniophores and antheridiophores. After fertilization and development, the needlelike sporophyte projects out of the gametophyte thallus, forming a spike or “horn,” hence the name *hornwort*. A single gametophyte often produces multiple sporophytes (FIG. 27-10). Meiosis occurs,

Figure 27-10 Bryophytes: hornworts

The gametophyte of the common hornwort (*Anthoceros natans*) is a small thallus with unicellular rhizoids on the lower (ventral) surface. After fertilization, sporophytes project up out of the gametophyte, forming “horns.”

forming spores within each **sporangium** (pl., *sporangia*), or spore case. The sporangium splits open from the top to release the spores; each spore can give rise to a new gametophyte thallus. A unique feature of hornworts is that the sporophytes, unlike those of mosses and liverworts, continue to grow from their bases for the remainder of the gametophyte’s life, a characteristic known as **indeterminate growth**. Some botanists think that indeterminate growth may indicate that hornworts evolved from plants with larger, more complex sporophytes.

Bryophytes are used for experimental studies

Botanists use certain bryophytes as experimental models to study many fundamental aspects of plant biology, including genetics, growth and development, plant ecology, plant hormones, and *photoperiodism*, which is plant responses to varying periods of night and day length.

The moss *Physcomitrella patens* is a particularly important research organism for studying plant evolution because its features and genome can be compared with those of algae and flowering plants (FIG. 27-11). In this regard *Physcomitrella* is a plant equivalent of the fruit fly *Drosophila*, which is an important model organism for studies of animal inheritance, development, and evolution. As experimental organisms,

Does the *Physcomitrella* genome reveal any insights in plant evolution?

HYPOTHESIS: Comparing the genome of the model organism *Physcomitrella* with genomes of other land plants as well as green algae will provide details of genes that were probably associated with the colonization of land.

EXPERIMENT: Several dozen scientists in Germany, the United States, Japan, the United Kingdom, Australia, Canada, and Belgium collaborated to produce the draft genome sequence for the model organism *Physcomitrella* (see photograph). This bryophyte was selected because researchers have used *Physcomitrella* in a wide variety of experiments and have a good understanding of its biology.

After sequencing the genome of *Physcomitrella*, it was compared with available genomes of green algae (*Ostreococcus* and *Chlamydomonas*) and land plants: the model flowering plant *Arabidopsis*, rice (*Oryza sativa*), and western balsam poplar (*Populus trichocarpa*).

Courtesy of David J. Cove, University of Leeds

Figure 27-11 The moss *Physcomitrella*, the first bryophyte to have its genome sequenced

RESULTS AND CONCLUSION: Researchers found that *Physcomitrella* has lost some genes needed for life in the water and gained new genes needed for life on land. Every land plant has to meet the same environmental challenges, such as obtaining enough water and preventing excessive water loss, tolerating high and low temperatures, and adapting to increased levels of solar radiation. These challenges have resulted in many modifications in plant body plans and physiological processes.

Bryophytes and vascular plants living today represent remnants of the first plants that colonized land some 450 mya. Compared with green algae, *Physcomitrella* lacks the genes needed to survive in aquatic environments but has gained genes involving plant signaling molecules (auxin, abscisic acid, and cytokinins) needed to adapt to drought, extremes of temperature, and light reception. Compared with *Physcomitrella*, other land plants have gained additional signaling molecules (gibberellins, jasmonic acid, and brassinosteroids) that enable a more complex tolerance of environmental stressors.

Because of its intermediary position in evolution (i.e., between green algae and vascular land plants), *Physcomitrella*'s genome allows biologists to reconstruct which genes may have been acquired and lost during the colonization of land by the last common ancestor of all land plants.

SOURCE: Rensing, S.A., et al., "The *Physcomitrella* Genome Reveals Evolutionary Insights into the Conquest of Land by Plants," *Science*, Vol. 319 (Jan. 4, 2008): 64–69.

PREDICT Would you expect *Physcomitrella* to possess genes required to produce xylem or phloem?

Physcomitrella and other bryophytes are easy to grow on artificial media and do not require much space because they are so small.

Recap: details of bryophyte evolution are based on fossils and on structural and molecular evidence

Plants are a **monophyletic group**; that is, all plants probably evolved from a common ancestral green alga. Fossil evidence indicates that bryophytes are ancient plants, probably the first group of plants to arise from the common plant ancestor. The fossil record of ancient bryophytes is incomplete, consisting mostly of spores and small tissue fragments, and can be interpreted in different ways. As a result, it does not provide a definite answer on bryophyte evolution.

The oldest known recognizable plant fossils are dated at about 425 million years old. These fossils resemble modern liverworts in many respects, but the spores are virtually identical to those in 470-million-year-old rocks. Fossil fragments of tiny liverwort-like plants associated with ancient spores have been discovered in Oman. This evidence suggests that liverwort-like plants may have been the earliest plants to colonize land.

CHECKPOINT 27.2

- Which of the following are parts of the gametophyte generation in mosses: antheridia, zygote, embryo, capsule, archegonia, sperm cells, egg cell, spores, and protonema?
- **CONNECT** How are mosses, liverworts, and hornworts similar? How is each group distinctive?

27.3 Seedless Vascular Plants

LEARNING OBJECTIVES

- Discuss the features that distinguish seedless vascular plants from algae and bryophytes.
- Name and briefly describe the two phyla of seedless vascular plants.
- Describe the life cycle of ferns and compare their sporophyte and gametophyte generations.
- Compare the generalized life cycles of homosporous and heterosporous plants.

The most important adaptation found in seedless vascular plants, although absent in algae and bryophytes, is specialized vascular tissues—xylem and phloem—for support and conduction. This system of conduction lets vascular plants grow larger than bryophytes because water, minerals, and sugar are transported to all parts of the plant. Although seedless vascular plants in temperate environments are relatively small, tree ferns in the tropics may grow to heights of 18 m (60 ft). All seedless vascular plants have true stems with vascular tissues, and most also have true roots and leaves.

(a) Microphyll evolution. Microphylls probably originated as outgrowths (enations) of stem tissue that developed a single vascular strand later. Club mosses have microphylls.

(b) Megaphyll evolution. Megaphylls probably evolved from the evolutionary modification of side branches. Webbing is the evolutionary process in which the spaces between close branches become filled with chlorophyll-containing cells. Ferns, horsetails, gymnosperms, and flowering plants have megaphylls.

Figure 27-12 Evolution of microphylls and megaphylls

Botanists have extensively studied the evolution of the leaf as the main organ of photosynthesis. The two basic types of true leaves—microphylls and megaphylls—evolved independently of each other (FIG. 27-12). The **microphyll**, which is usually small and has a single vascular strand, probably evolved from small, projecting extensions of stem tissue (*enations*). Only one group of living plants, the club mosses, has microphylls.

In contrast, **megaphylls** probably evolved from stem branches that gradually filled in with additional tissue (*webbing*) to form most leaves as we know them today. Megaphylls have more than one vascular strand, as we would expect if they evolved from branch systems. Ferns (with the exception of whisk ferns, discussed later in this chapter), gymnosperms, and flowering plants have megaphylls.

Recent evidence suggests megaphylls evolved over a 40-million-year period in the Late Paleozoic era in response to a gradual decline in the level of atmospheric CO₂. As CO₂ declined, plants developed a flattened blade with more stomata for gas exchange. (More stomata allowed cells inside the leaf to get enough CO₂.)

There are two main clades of seedless vascular plants: the club mosses and the ferns. Biologists originally considered horsetails and whisk ferns distinct enough to be classified in separate phyla. However, many kinds of evidence, such as DNA comparisons and similarities in sperm structure, have resulted in their being reclassified as ferns. As shown in FIGURE 27-13, ferns, including horsetails and whisk ferns, are a monophyletic group and the closest living relatives of seed plants (also see Table 27-2).

Club mosses are small plants with rhizomes and short, erect branches

Club mosses (phylum Lycopodiophyta) were important plants millions of years ago, when species that are now extinct often reached great size (FIG. 27-14a). These large, treelike plants were major

Key Point

Seedless vascular plants include lycophytes and ferns.

Figure 27-13 Evolutionary relationships among extant seedless vascular plants

These relationships are based on structural and molecular comparisons.

CONNECT According to the cladogram, which group, the lycophytes or the ferns, is most closely related to the seed plants?

contributors to our present-day coal deposits (see *Inquiring About: Ancient Plants and Coal Formation* on page 579).

The 1200 or so species of club mosses living today, such as *Lycopodium* (FIG. 27-14b), are small (less than 25 cm, or 10 in., tall), attractive plants common in temperate woodlands. They possess true roots, both rhizomes and erect aerial stems, and small, scalelike leaves (microphylls). Sporangia are borne on reproductive leaves that are either clustered in conelike strobili at the tips of stems or scattered in reproductive areas along the stem. Club mosses are evergreen and often fashioned into wreaths and other decorations. In some areas they are endangered by overharvesting.

That common names are sometimes misleading in biology is vividly evident in this group of plants. The most common names for the phylum Lycopodiophyta are “club mosses” and “ground pines,” yet these plants are neither mosses, which are nonvascular, nor pines, which are seed plants.

Ferns are a diverse group of spore-forming vascular plants

Most of the 11,000 species of **ferns** (phylum Pteridophyta) are terrestrial, although a few have adapted to aquatic habitats. Ferns range from the tropics to the Arctic Circle, with most species living in tropical rain forests, where they perch high in the branches of trees. In temperate regions ferns commonly inhabit swamps, marshes, stream banks, and moist woodlands (FIG. 27-15a). Some species grow in fields, rocky crevices on cliffs or mountains, or even deserts.

The life cycle of ferns involves a clearly defined alternation of generations. The ferns grown as houseplants (e.g., Boston fern, maiden-hair fern, and staghorn fern) represent the larger, more conspicuous sporophyte generation.

The fern sporophyte consists of a horizontal underground stem, or *rhizome*, that bears leaves, called *fronds*, and true roots. As each young frond first emerges from the ground, it is tightly coiled and resembles the top of a violin, hence the name *fiddlehead* (FIG. 27-15b). As fiddleheads grow, they unroll and expand to form fronds. Fern fronds are usually compound (the blade is divided into leaflets), with the leaflets forming beautifully complex leaves. Fronds, roots, and rhizomes all contain vascular tissues.

Spore production usually occurs in certain areas on the fronds, which develop sporangia. Many species bear the sporangia in clusters, called **sori** (sing., *sorus*) (FIGS. 27-15c and d). Within sporangia, sporogenous cells (spore mother cells) undergo meiosis to form haploid spores. The sporangia burst open and discharge spores that may germinate and grow by mitosis into gametophytes.

The mature fern gametophyte, which bears no resemblance to the sporophyte, is a tiny (less than half the size of one of your fingernails), green, often heart-shaped structure that grows flat against the ground. Called a **prothallus** (pl., *prothalli*), the fern gametophyte lacks vascular tissues and has tiny, hairlike absorptive rhizoids to anchor it (FIG. 27-15e). The prothallus usually produces both archegonia and antheridia on its underside. Each archegonium contains a single egg, whereas numerous sperm cells are produced in each antheridium.

Ferns use water as a transport medium. The flagellate sperm cells swim, usually from a nearby prothallus, to the neck of an archegonium through a thin film of water on the ground underneath the prothallus. After one of the sperm cells fertilizes the egg, a diploid zygote grows by mitosis into a multicellular embryo (an immature sporophyte). At this stage, the sporophyte embryo is attached to and dependent on the gametophyte. As the embryo matures, however, the prothallus withers and dies, and the sporophyte becomes free-living.

The fern life cycle alternates between the dominant, diploid sporophyte with its rhizome, roots, and fronds and the haploid gametophyte (prothallus) (FIG. 27-16 on page 578). The sporophyte generation is dominant not only because it is larger than the gametophyte but also because it persists for an extended period (most fern sporophytes are perennials), whereas the gametophyte dies soon after reproducing.

Whisk ferns are classified as reduced ferns

Only about 12 species of **whisk ferns** (phylum Pteridophyta) exist today, and the fossil record contains several extinct species. Whisk ferns, which live mainly in the tropics and subtropics, are relatively simple in structure and lack true roots and leaves but have vascularized stems. *Psilotum nudum*, a representative whisk fern, has both a horizontal underground rhizome and vertical aerial stems (FIG. 27-17a). Whenever the stem forks, or branches, it always divides into two equal halves. Botanists call this forking **dichotomous branching**. In contrast, when most plant stems branch, one stem is more vigorous and becomes the main trunk.

The upright stems of *Psilotum* are green and are the main organs of photosynthesis. Tiny, round sporangia, borne directly on the erect, aerial stems, contain sporogenous cells that undergo meiosis to form haploid spores. After dispersal, the spores germinate to form haploid prothalli. Because they grow underground, the prothalli of whisk ferns are difficult to study (FIG. 27-17b). They are nonphotosynthetic as a result of their subterranean location, and they apparently have a symbiotic relationship with mycorrhizal fungi that provides them with sugar and essential minerals (see Chapter 29).

Botanists have carefully studied whisk ferns in recent years. Molecular data, including comparisons of nucleotide

sequences of ribosomal RNA, chloroplast DNA, and mitochondrial DNA in living species, support the hypothesis that the whisk ferns should be classified as reduced ferns rather than as surviving representatives of extinct vascular plants (see discussion of rhyniophytes later in this chapter).

Horsetails are an evolutionary line of ferns

About 300 mya, the **horsetails** (phylum Pteridophyta) were among the dominant plants and grew as large as modern trees (FIG. 27-18a on page 580). Because they contributed to Earth's vast coal deposits, these ancient horsetails, like ancient club mosses, are still significant today.

The few surviving horsetails, about 15 species in the genus *Equisetum*, grow mostly in wet, marshy habitats and are less than 1.3 m (4 ft) tall, but extremely distinctive (FIG. 27-18b on page 580). They are widely distributed on every continent except Australia. Traditionally classified in their own phylum, horsetails are now grouped with ferns. This reclassification is based on molecular similarities between horsetails and other ferns.

Horsetails have true roots, stems (both rhizomes and erect aerial stems), and small leaves. The hollow, jointed stems are impregnated with silica, which gives them a gritty texture. Small leaves, interpreted as reduced megaphylls, are fused in whorls at each node (the area on the stem where leaves attach). The

Figure 27-15 Seedless vascular plants: ferns

green stem is the main organ of photosynthesis. Horsetails are so named because certain vegetative (nonreproductive) stems have whorls of branches that give the appearance of a bushy horse's tail. In the past, horsetails were called "scouring rushes" and were used to scrub pots and pans along stream banks.

Each reproductive branch of a horsetail bears a terminal conelike **strobilus** (pl., *strobili*). The strobilus consists of several stalked, umbrella-like structures, each of which bears five to ten sporangia in a circle around a common axis.

The horsetail life cycle is similar in many respects to the fern life cycle. In horsetails, as in ferns, the sporophyte is the conspicuous plant, whereas the gametophyte is a minute, lobed thallus ranging in width from the size of a pinhead to about 1 cm across. The sporophyte and gametophyte are both photosynthetic and nutritionally independent at maturity. Like ferns, horsetails require water as a medium for flagellate sperm cells to swim to the egg.

Some ferns and club mosses are heterosporous

In the life cycles examined thus far, plants produce only one type of spore as a result of meiosis. This condition, known as **homospory**, is characteristic of bryophytes, horsetails, whisk ferns, and most ferns and club mosses. However, certain ferns and club mosses (known as spike mosses) exhibit **heterospory**, in which they produce two types of spores: microspores and megaspores.

FIGURE 27-19 on page 581 illustrates the generalized life cycle of a heterosporous plant. The sporophyte plant produces sporangia within a conelike strobilus. Each strobilus usually bears two kinds of sporangia: microsporangia and megasporangia. *Microsporangia* are sporangia that produce *microsporocytes* (also called *microspore mother cells*), which undergo meiosis to form microscopic, haploid **microspores**. Each microspore develops into a male gametophyte that produces sperm cells within antheridia.

The dominant phase in the life cycle of ferns, like that of all other vascular plants, is the sporophyte.

Figure 27-16 The life cycle of ferns

Note the clearly defined alternation of generations between the gametophyte (prothallus) and sporophyte (leafy plant) generations.

CONNECT What is the most fundamental difference between the fern life cycle and that of mosses?

Megasporangia produce *megasporocytes* (also called *megaspore mother cells*). When megasporocytes undergo meiosis, they form haploid **megaspores**, each of which develops into a female gametophyte that produces eggs in archegonia.

The development of male gametophytes from microspores and of female gametophytes from megaspores occurs within their respective spore walls, using stored food provided by the sporophyte. As a result, and unlike the gametophytes of other seedless vascular plants, the male and female gametophytes are not truly free-living. Fertilization is followed by the development of a new sporophyte.

Heterospory evolved several times during the history of land plants. It was a significant development in plant evolution because it was the forerunner of the evolution of seeds. Heterospory characterizes the two most successful groups of plants existing today, the gymnosperms and the flowering plants, both of which produce seeds.

Seedless vascular plants are used for experimental studies

Botanists use many seedless vascular plants as experimental models to study certain aspects of plant biology, such as

Inquiring About

Ancient Plants and Coal Formation

How did the coal that industrial society uses as an energy source form? Coal, which is burned to produce electricity and to manufacture items of steel and iron, is one of the most important fossil fuels. Although mined, coal is not an inorganic mineral like gold or aluminum but rather is an organic material formed from the remains of ancient vascular plants, particularly those of the Carboniferous period, approximately 320 mya. Four main groups of plants contributed to coal formation. Two were seedless vascular plants: the club mosses and ferns (see figure), including horsetails. The other two were seed plants: seed ferns (now extinct) and early gymnosperms.

It is hard to imagine that relatives of the small, relatively inconspicuous club mosses, ferns, and horsetails of today were so significant in forming vast beds of coal. However, many members of these groups that existed during the Carboniferous period were giants compared with their modern counterparts and formed immense forests. (Figure 21-12 shows a reconstruction of a Carboniferous forest.)

The climate during the Carboniferous period was warm, moist, and mild. Plants in most

locations could grow year-round because of the favorable conditions. Forests of these plants often grew in low-lying, swampy areas that periodically flooded when the sea level rose. As the sea level receded, these plants would re-establish.

When these large plants died or were blown over in storms, they decomposed incompletely because they were covered by swamp water. (The anaerobic conditions of the water prevented wood-rotting fungi from decomposing the plants, and anaerobic bacteria do not decompose wood rapidly.) Thus, over time the partially decomposed plant material accumulated and consolidated.

Layers of sediment formed over the plant material each time the water level rose and flooded the low-lying swamps. With time, heat and pressure built up in these accumulated layers and converted the plant material to coal and the sediment layers to sedimentary rock. Much later, geologic upheavals raised the layers of coal and sedimentary rock. Coal is usually found in seams, underground layers that vary in thickness from 2.5 cm (1 in.) to more than 30 m (100 ft).

The various grades of coal (lignite, the lowest grade; subbituminous; bituminous;

David Lyons/Alamy Stock Photo

This piece of Carboniferous coal contains a fossilized fern. The coal and fossil are about 300 million years old.

and anthracite, the highest grade) formed as a result of the different temperatures and pressures to which the layers were exposed. Coal exposed to high heat and pressure during its formation is drier, is more compact (and therefore harder), and has a higher heating value (i.e., a higher energy content) than coal exposed to lower heat and temperature conditions.

physiology, growth, and development. Ferns and other seedless vascular plants are useful in studying how apical meristems give rise to plant tissues. An **apical meristem** is the area at the tip (apex) of a root or shoot where growth—cell division, elongation, and differentiation—occurs. Ferns and other seedless vascular plants have a single large *apical cell* located at the center tip of the apical meristem. This apical cell is the source, by mitosis, of all the cells that eventually make up the root or shoot. The apical cell divides in an orderly fashion, and the smaller daughter cells produced by the apical

cell, in turn, divide and give rise to different parts of the root or shoot. It is possible to trace mature cells in the root or shoot back to their origin from the single apical cell.

Ferns are interesting research plants for studies in genetics because they are **polyploids** and have multiple sets of chromosomes. (Many ferns have hundreds of chromosomes.) However, gene expression in ferns is exactly what one would expect of a *diploid* plant. Apparently, genes in the extra sets of chromosomes are gradually silenced and therefore not expressed.

John Arnold

(b) *Equisetum telematia*, a horsetail with a wide distribution in Eurasia, Africa, and North America, has unbranched reproductive shoots bearing conelike strobili and separate, highly branched vegetative (nonreproductive) shoots. In some horsetail species, both reproductive and vegetative shoots are unbranched.

Figure 27-18 Horsetails

Seedless vascular plants arose more than 420 mya

Currently, the oldest known megafossils of early vascular plants are from Silurian (420 mya) deposits in Europe. (Plant *megafossils* are fossilized roots, stems, leaves, and reproductive structures.) Megafossils of several kinds of small, seedless vascular plants also occur in Silurian deposits in Bolivia, Australia, and northwestern China. Microscopic spores of early vascular plants appear in the fossil record earlier than megafossils, suggesting that even older megafossils of simple vascular plants may be discovered.

Botanists assign the oldest vascular plants to phylum Rhyniophyta, which, according to the fossil record, arose some 420 mya and became extinct about 380 mya. The rhyniophytes are so named because many fossils of these extinct plants were found in fossil beds near Rhynie, Scotland. *Rhynia gwynne-vaughanii* is an example of an early vascular plant that superficially resembled whisk ferns in that it consisted of leafless upright stems that branched dichotomously from an underground rhizome (FIG. 27-20). *Rhynia* lacked roots, although it had absorptive rhizoids. Sporangia formed at the ends of short branches. The internal structure of its rhizome contained a central core of xylem cells for conducting water and minerals.

For many years, botanists considered *Rhynia major*, a plant that grew about 50 cm (20 in.) tall and probably lived in marshes, a classic example of a rhyniophyte. Fossils indicate that this plant had rhizoids, dichotomously branching rhizomes, and upright stems that terminated in sporangia. However, recent microscopic studies of fossil rhizomes indicate

that the central core of tissue lacked the xylem cells characteristic of vascular plants. For that reason, *R. major* was reclassified into a new genus, *Aglaophyton*, and is no longer considered a rhyniophyte (FIG. 27-21).

The oldest known megafossils of fernlike trees, discovered in New York, are dated at 380 million years old. These trees, which were about 8 m (26 ft) tall, had vascular tissues but no leaves and a minimal root system. They grew vertically and reproduced by forming spores. The trunks were discovered in the late 1800s (and named *Eospermatopteris*), but not until 2007 was a fossil of an entire tree pieced together. The tree-tops had previously been found separate from the trunks and named *Wattieza*.

CHECKPOINT 27.3

- What adaptations do ferns have that both algae and bryophytes lack?
- **CONNECT** How does one distinguish between megaphylls and microphylls?
- Which of the following are parts of the sporophyte generation in ferns: frond, sperm cells, egg cell, roots, sorus, sporangium, spores, prothallus, rhizome, antheridium, archegonium, and zygote?
- Why are whisk ferns and horsetails now classified as ferns?
- How does heterospory modify the plant life cycle?

Key Point

Heterospory—the production of two types of spores—was the forerunner of the evolution of seeds.

Figure 27-19 The basic life cycle of heterosporous plants

Two types of spores, microspores and megaspores, are produced during the life cycle of heterosporous plants.

CONNECT What fundamental similarities does a heterosporous life cycle share with the basic plant life cycle depicted in Figure 27-2?

Figure 27-20
Reconstruction of *Rhynia gwynne-vaughanii*

This leafless plant, one of Earth's earliest vascular plants, is now extinct. It grew about 18 cm (7 in.) tall. Redrawn from Edwards, D., "Evidence for the Sporophytic Status of the Lower Devonian Plant *Rhynia gwynne-vaughanii*," *Review of Palaeobotany and Palynology*, Vol. 29 (1980).

Figure 27-21 Reconstruction of *Aglaophyton major*

Recent evidence indicates that this plant, although superficially similar to other early vascular plants, lacked conducting tissues that are characteristic of vascular plants. For this reason, it has been reclassified into a new genus and is no longer considered a rhyniophyte. Redrawn from Mauseth, J.D., *Botany: An Introduction to Plant Biology*, 2nd ed. (Saunders College Publishing, Philadelphia, 1995).

Summary: Focus on Learning Objectives

27.1 Adaptations of Plants to Life on Land (page 564)

1 Discuss some environmental challenges of living on land and describe how several plant adaptations meet these challenges.

- The colonization of land by plants required the evolution of many anatomical, physiological, and reproductive adaptations. Plants have a waxy **cuticle** to protect against water loss and **stomata** for gas exchange needed for photosynthesis.
- Plant life cycles have an **alternation of generations** in which they spend part of their life cycle in a multicellular haploid **gametophyte generation** and part in a multicellular diploid **sporophyte generation**. The gametophyte plant produces gametes by mitosis. During fertilization these gametes fuse to form a **zygote**, the first stage of the sporophyte generation. The zygote develops into a multicellular **embryo** that the gametophyte protects and nourishes. The mature sporophyte plant develops from the embryo and produces sporogenous cells (spore mother cells). These cells undergo meiosis to form **spores**, the first stage in the gametophyte generation.
- Most plants have multicellular **gametangia** with a protective jacket of sterile cells surrounding the gametes. **Antheridia** are gametangia that produce sperm cells, and **archegonia** are gametangia that produce eggs.
- Ferns and other vascular plants have **xylem** to conduct water and dissolved minerals and **phloem** to conduct dissolved sugar.

2 Name the green algal group from which plants are hypothesized to have descended and describe supporting evidence.

- Plants probably arose from a group of green algae called **charophytes**. This conclusion is based in part on molecular comparisons of DNA and RNA sequences, which show the closest match between charophytes and plants.

27.2 Bryophytes (page 568)

3 Summarize the features that distinguish bryophytes from other plants.

- Unlike other land plants, **bryophytes** are nonvascular and lack xylem and phloem. Bryophytes are the only plants with a dominant gametophyte generation. Their sporophytes remain permanently attached and nutritionally dependent on the gametophytes.

4 Name and briefly describe the three phyla of bryophytes.

- **Mosses** (phylum Bryophyta) have gametophytes that are green plants that grow from a filamentous **protonema**.
- Many **liverworts** (phylum Hepatophyta) have gametophytes that are flattened, lobelike **thalli**; others are leafy.
- **Hornworts** (phylum Anthocerophyta) have thalloid gametophytes.

5 Describe the life cycle of mosses and compare their gametophyte and sporophyte generations.

- The green moss gametophyte bears archegonia, antheridia, or both at the top of the plant. During fertilization,

a sperm cell fuses with an egg cell in the archegonium. The zygote grows into an embryo that develops into a moss sporophyte, which is attached to the gametophyte. Meiosis occurs within the capsule of the sporophyte to produce spores. When a spore germinates, it grows into a protonema that forms buds that develop into gametophytes.

27.3 Seedless Vascular Plants (page 574)

6 Discuss the features that distinguish seedless vascular plants from algae and bryophytes.

- Seedless vascular plants have several adaptations that algae and bryophytes lack, including vascular tissues and a dominant sporophyte generation. As in bryophytes, reproduction in seedless vascular plants depends on water as a transport medium for motile sperm cells.

7 Name and briefly describe the two phyla of seedless vascular plants.

- Sporophytes of **club mosses** (phylum Lycopodiophyta) consist of roots, rhizomes, erect branches, and leaves that are **microphylls**.
- **Ferns** (phylum Pteridophyta) are the largest and most diverse group of seedless vascular plants. The fern sporophyte consists of a rhizome that bears fronds and true roots. Phylum Pteridophyta also includes whisk ferns and horsetails. Sporophytes of **whisk ferns** have **dichotomously branching** rhizomes and erect stems; they lack true roots and leaves. **Horsetail** sporophytes have roots, rhizomes, aerial stems that are hollow and jointed, and leaves that are reduced **megaphylls**.

8 Describe the life cycle of ferns and compare their sporophyte and gametophyte generations.

- Fern sporophytes have roots, rhizomes, and leaves that are megaphylls. Their leaves, or fronds, bear sporangia in clusters called **sori**. Meiosis in sporangia produces haploid spores. The fern gametophyte, called a **prothallus**, develops from a haploid spore and bears both archegonia and antheridia.

9 Compare the generalized life cycles of homosporous and heterosporous plants.

- **Homospory**, the production of one kind of spore, is characteristic of bryophytes, most club mosses, and most ferns, including whisk ferns and horsetails. In homospory, spores give rise to gametophyte plants that produce both egg cells and sperm cells.
- **Heterospory**, the production of two kinds of spores (microspores and megaspores), occurs in certain club mosses, certain ferns, and all seed plants. **Microspores** give rise to male gametophytes that produce sperm cells. **Megaspores** give rise to female gametophytes that produce eggs. The evolution of heterospory was an essential step in the evolution of seeds.

Test Your Understanding

Know and Comprehend

1. Plants probably descended from a group of green algae called (a) rhyniophytes (b) *Calamites* (c) epiphytes (d) charophytes (e) club mosses
2. Which of the following is *not* a characteristic of plants? (a) cuticle (b) unicellular gametangia (c) stomata (d) multicellular embryo (e) alternation of generations
3. In plant life cycles, (a) the first products of meiosis are gametes (b) spores are part of the diploid sporophyte generation (c) the embryo gives rise to a zygote (d) the first stage in the diploid sporophyte generation is the zygote (e) the first stage in the haploid gametophyte generation is the prothallus
4. The bryophytes (a) include mosses, liverworts, and hornworts (b) include whisk ferns, horsetails, and club mosses (c) are small plants that lack a vascular system (d) a and c (e) b and c
5. The waxy layer that covers aerial parts of plants is the (a) cuticle (b) archegonium (c) protonema (d) stoma (e) thallus
6. A strengthening compound found in cell walls of vascular plants is (a) chitin (b) lignin (c) cutin (d) cellulose (e) carotenoid
7. Stomata (a) help prevent desiccation of plant tissues (b) transport water and minerals through plant tissues (c) allow gas exchange for photosynthesis (d) strengthen cell walls (e) produce male gametes
8. The green, gametangia-bearing moss plant (a) is the haploid gametophyte generation (b) is the diploid sporophyte generation (c) is called a protonema (d) contains cells with single large chloroplasts (e) b and c
9. A(n) _____ is a leaf that arose from a branch system. (a) antheridium (b) microphyll (c) megaphyll (d) sorus (e) microspore
10. These plants have vascularized stems but lack true roots and leaves. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts

11. These plants have hollow, jointed stems that are impregnated with silica. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
12. Which of the following statements about ferns is *not* true? (a) ferns have motile sperm cells that swim through water to the egg-containing archegonium (b) ferns are vascular plants (c) ferns are the most economically important group of bryophytes (d) the fern sporophyte consists of a rhizome, roots, and fronds (e) the diversity of ferns is greatest in the tropics

Apply and Analyze

13. **VISUALIZE** Draw a simple diagram illustrating a heterosporous life cycle. Include the sporophyte generation, megaspore, female gametophyte, egg, microspore, male gametophyte, sperm, meiosis, and fertilization. Be sure to indicate whether each generation or kind of cell is haploid or diploid.

Evaluate and Synthesize

14. **EVOLUTION LINK** How may the following trends in plant evolution be adaptive to living on land? (a) dependence on water for fertilization → no need for water as a transport medium (b) homosporous → heterosporous
15. **INTERPRET DATA** According to the cladogram in Figure 27-5, which plants evolved first: nonvascular bryophytes, seedless vascular plants, or seed plants?
16. **EVOLUTION LINK** Where would you position the rhyniophytes on Figure 27-13? Would the line for rhyniophytes extend to the tips of the rest of the cladogram? Why or why not?

28 Seed Plants

KEY CONCEPTS

- 28.1** Seed plants, which produce young sporophytes enclosed within seeds, include gymnosperms and angiosperms.
- 28.2** Gymnosperms produce exposed ovules that, following fertilization, develop into seeds that are usually borne in cones on the sporophytes. Conifers are the most diverse and numerous of the four living gymnosperm phyla.
- 28.3** Angiosperms produce ovules enclosed within carpels; following fertilization, seeds develop from the ovules, and the ovaries of carpels become fruits. Angiosperms dominate the land and exhibit great diversity in both vegetative and reproductive structures.
- 28.4** Gymnosperms evolved from ancestral seedless vascular plants; angiosperms evolved from ancestral gymnosperms, possibly an ancient conifer.

Chapter 27 focused on plants that reproduce by means of *spores*, haploid cells that disperse and germinate to produce gametophytes. Although gymnosperms and angiosperms also produce spores, their primary means of reproduction and dispersal is by **seeds**, which represent an important adaptation for life on land (see photograph). Each seed consists of an embryonic sporophyte, nutritive tissue, and a protective coat. Seeds develop from the fertilized egg cell, the female gametophyte, and its associated tissues. The two groups of seed plants, gymnosperms and angiosperms (flowering plants), exhibit the greatest evolutionary complexity of land plants and are the dominant plants in most terrestrial environments.

Seeds are reproductively superior to spores for several reasons. First, a seed is further along in its development before it is released to survive on its own: a seed contains a multicellular young plant with embryonic root, stem, and one or more leaves already formed, whereas a spore is a single cell. Second, a seed contains an abundant food supply. After germination, food stored in the seed nourishes the plant embryo until it becomes self-sufficient. Because a spore is a single cell, few food reserves exist for the plant that develops from a spore. Third, a seed is protected by a multicellular **seed coat** that is very thick and hard in some plants, as, for example, in lima beans. Like spores, seeds live for extended periods at reduced rates of metabolism and germinate when conditions become favorable.

Seeds and seed plants are intimately connected with the development of human civilization. From prehistoric times, early humans collected and used seeds for food. Seeds often contain a

PHOTO: Wild tamarind (*Cajuputa arborea*) seeds. The black seeds develop in the seed pods (fruits), which turn orange as they ripen.

Jillian Cain Photography/Shutterstock.com

concentrated source of proteins, oils, carbohydrates, and vitamins, which are nourishing for humans as well as for germinating plants. Seeds are easy to store (if kept dry), so humans can collect them during times of plenty to save for times of need. Few other foods are stored as conveniently or for as long. Although flowering plants produce most seeds that humans consume, the seeds of certain gymnosperms—the piñon pine, for example—are edible.

In this chapter we present the diversity in seed plants—both gymnosperms and angiosperms—followed by an examination of what we know about how seed plants evolved.

28.1 An Introduction to Seed Plants

LEARNING OBJECTIVE

- 1 Compare the features of gymnosperms and angiosperms.

Like the bryophytes and seedless vascular plants introduced in Chapter 27, seed plants have life cycles with an **alternation of generations**; they spend part of their lives in the multicellular diploid sporophyte stage and part in the multicellular haploid gametophyte stage. The sporophyte generation is the dominant stage in seed plants, and the gametophyte generation is significantly reduced in size and entirely dependent on the sporophyte generation. Unlike the bryophytes and ferns, seed plants do not have free-living gametophytes. Instead, the female gametophyte is attached to and nutritionally dependent on the sporophyte generation.

In Chapter 27 you learned that some seedless vascular plants are heterosporous. (Figure 27-19 shows a generalized life cycle for heterosporous plants.) However, *all* seed plants are heterosporous and produce two types of spores: microspores and megaspores. In fact, heterospory is a requirement of seed production.

Seed plants produce **ovules**, each of which is a *megasporangium* surrounded by **integuments**, layers of sporophyte tissue that enclose the megasporangium. After fertilization takes place, the ovule develops into a seed, and the integuments develop into the seed coat (**FIG. 28-1a**).

Botanists divide seed plants into two groups based on whether or not an ovary wall surrounds their ovules (an *ovary* is a structure that contains one or more ovules). The two groups of seed plants are the **gymnosperms** and the **angiosperms** (**TABLE 28-1**). The word *gymnosperm* is derived from the Greek for “naked seed.” Gymnosperms produce seeds that are totally exposed or borne on the scales of cones (**FIG. 28-1b**). In other words, an ovary wall does not surround the ovules of gymnosperms. Pine, spruce, fir, hemlock, and ginkgo are examples of gymnosperms.

The term *angiosperm* is derived from the Greek expression that means “seed enclosed in a vessel or case.” Angiosperms are flowering plants that produce their seeds within a *fruit* (a mature ovary) (**FIG. 28-1c**). Thus, the ovules of angiosperms are protected. Flowering plants, which are extremely diverse, include corn, oaks, water lilies, cacti, apples, grasses, palms, and buttercups.

Both gymnosperms and flowering plants have vascular tissues: **xylem**, for conducting water and dissolved minerals (inorganic nutrients), and **phloem**, for conducting dissolved sugar.

(a) **Gymnosperm seed.** Longitudinal section through a pine seed.

(b) **Gymnosperm cone.** Longitudinal section through a female pine cone, showing the ovules (which develop into seeds) borne on scales. Note the absence of an ovary wall.

(c) **Angiosperm fruit.** Longitudinal section through an avocado fruit, showing the seed surrounded by ovary tissue of the maternal sporophyte.

Figure 28-1 Seeds

Table 28-1 A Comparison of Gymnosperms and Angiosperms

Characteristic	Gymnosperms	Angiosperms
		
Growth habit	Woody trees and shrubs	Woody or herbaceous
Conducting cells in xylem	Tracheids	Vessel elements and tracheids
Reproductive structures	Cones (usually)	Flowers
Pollen grain transfer	Wind (usually)	Animals or wind
Fertilization	Egg and sperm → zygote	Double fertilization: egg and sperm → zygote; two polar nuclei and sperm → endosperm
Seeds	Exposed or borne on scales of cones	Enclosed within fruit derived from ovary
Nutritive material	Female gametophyte	Endosperm
Number of species	About 840	More than 300,000
Geographic Distribution	Worldwide	Worldwide

commonly called conifers. Two phyla of gymnosperms, Ginkgophyta (the ginkgoes) and Cycadophyta (the cycads), are evolutionary remnants of groups that were more significant in the past. The fourth phylum, Gnetophyta (gnetophytes), is a collection of some unusual plants that share certain traits not found in other gymnosperms; until recently, the gnetophytes were thought to be more closely related to flowering plants than were other gymnosperm clades. Current evidence, however, suggests that gnetophytes are probably most closely related to conifers (see Fig. 28-2).

Conifers are woody plants that produce seeds in cones

The **conifers** (phylum Coniferophyta), which include pines, spruces, hemlocks, and firs, are the most familiar group of gymnosperms (FIG. 28-3a).

These 630 species of woody trees or shrubs produce annual additions of secondary tissues (wood and bark); there are no herbaceous (nonwoody) conifers. The wood (*secondary xylem*) consists of **tracheids**, which are long, tapering cells with pits through which water and dissolved minerals move from one cell to another.

Many conifers produce **resin**, a viscous, clear or translucent substance consisting of several organic compounds that may protect the plant from attack by fungi or insects. The resin collects in resin ducts, tubelike cavities that extend throughout the roots, stems, and leaves. Cells lining the resin ducts produce and secrete resin.

Conifers generally have leaves called *needles* that are long, narrow, tough, and leathery (FIG. 28-3b). Most pines bear clusters of two to five needles, depending on the species. In a few conifers, such as American arborvitae, the leaves are scale-like and cover the stem (FIG. 28-3c). Most conifers are evergreen and bear their leaves throughout the year. Only a few, such as the dawn redwood, larch, and bald cypress, are deciduous and shed their needles at the end of each growing season.

Most conifers are **monoecious**: they have separate male and female reproductive parts in different locations on the same plant. These reproductive parts are generally borne in *strobili* (commonly called *cones*), hence the name *conifer*, which means “cone-bearing.”

Conifers occupy extensive areas, ranging from the Arctic to the tropics, and are the dominant vegetation in the forested regions of Alaska, Canada, northern Europe, and Siberia. In addition, they are important in the Southern Hemisphere, particularly in wet, mountainous areas of temperate and tropical regions in South America, Australia, New Zealand, and Malaysia. Southwestern China, with more than 60 species of conifers, has the greatest regional diversity of conifer species

CHECKPOINT 28.1

- What is an ovule?
- What kinds of seeds are surrounded by an ovary wall?

28.2 Gymnosperms

LEARNING OBJECTIVES

- Trace the steps in the life cycle of a pine and compare its sporophyte and gametophyte generations.
- Summarize the features that distinguish gymnosperms from bryophytes and ferns.
- Name and briefly describe the four phyla of gymnosperms.

The gymnosperms include some of the most interesting plants. For example, a giant sequoia (*Sequoiadendron giganteum*) known as the General Sherman Tree, in Sequoia National Park in California, is one of the world's most massive organisms. It is 84.2 m (275 ft) tall and has a girth of 24.1 m (79 ft) measured 1.5 m (5 ft) above ground level. Another gymnosperm, a coast redwood (*Sequoia sempervirens*) nicknamed “Hyperion” after a giant in Greek mythology, is possibly the world's tallest tree, measuring 115.7 m (379 ft) in 2007. Botanists using tree-ring analysis determined that one of Earth's oldest living organisms, a bristlecone pine (*Pinus longaeva*) in the White Mountains of California, is about 5000 years old.

Gymnosperms are usually classified into four phyla, which branch from a single evolutionary line (FIG. 28-2). Numbering 630 species, the largest phylum of gymnosperms is Coniferophyta,

Key Point

Seed plants include four gymnosperm phyla and one phylum of flowering plants (angiosperms).

Figure 28-2 Gymnosperm and angiosperm evolution

This cladogram shows a current hypothesis of phylogenetic relationships among living seed plants, based on structural evidence, molecular comparisons, and fossils. Relationships among extant gymnosperm clades and angiosperms remain controversial. The arrangement of the phyla shown here may change as future analyses help clarify relationships.

CONNECT According to the cladogram, which group is most closely related to the conifers?

(a) White fir (*Abies concolor*). Photographed in Milford, Pennsylvania, at the historic home of Gifford Pinchot, the first Chief Forester of the U.S. Forest Service (under T. R. Roosevelt).

(b) In white pine (*Pinus strobus*), leaves are long, slender needles that occur in clusters of five.

(c) In American arborvitae (*Thuja occidentalis*), leaves are small and scalelike.

Figure 28-3 Conifers

Key Point

Gymnosperms, like all seed plants, are heterosporous.

Figure 28-4 Life cycle of pine

One major advantage of gymnosperms over the seedless vascular plants is the production of wind-borne pollen grains.

CONNECT Is a pine pollen grain haploid or diploid? Is it a gamete? Explain your answer.

in the world. California, New Caledonia (an island east of Australia), southeastern China, and Japan also have considerable diversity of conifer species. Ecologically, conifers contribute food and shelter to animals and other organisms, and their roots hold the soil in place and help prevent soil erosion.

Humans use conifers for their wood (for building materials as well as paper products), medicinal value (such as the anticancer drug Taxol from the Pacific yew), turpentine, and resins. Because of their attractive appearance, conifers such as

firs, spruces, pines, and cedars are grown for landscape design and decorative holiday trees and wreaths.

Pines represent a typical conifer life cycle

The genus *Pinus*, by far the largest genus in the conifers, consists of about 100 species. A pine tree is a mature sporophyte (FIG. 28-4). Pine is heterosporous and therefore produces

Figure 28-5 Male and female cones in lodgepole pine (*Pinus contorta*)

Mature woody female cones (top) have opened to shed their seeds. Clusters of male cones (bottom) produce copious amounts of pollen grains in the spring. (Inset) Each pollen grain develops from a microspore.

microspores and megaspores in separate cones. Male cones, usually 1 cm or less in length, are smaller than female cones and are generally produced on the lower branches each spring (FIG. 28-5). The more familiar, woody female cones, which are on the tree year-round, are usually found on the upper branches of the tree and bear seeds after reproduction. Female cones vary considerably in size. The sugar pine (*P. lambertiana*) that grows in California produces the world's longest female cones, which reach lengths of 60 cm (2 ft).

Each male cone, also called a **pollen cone**, consists of **sporophylls**, leaflike scales that bear sporangia on the underside. At the base of each sporophyll are two **microsporangia**, which contain numerous **microsporocytes**, also called *microspore mother cells*. In Figure 28-4, each microsporocyte undergoes meiosis to form four haploid microspores. **Microspores** then develop into extremely reduced male gametophytes. Each immature male gametophyte, also called a **pollen grain**, consists of four cells, two of which—a *generative cell* and a *tube cell*—are involved in reproduction. The other two cells soon degenerate. Two large air sacs on each pollen grain provide buoyancy for wind dissemination. Male cones shed pollen grains in great numbers, and wind currents carry some to the immature female cones.

Many botanists think that the female cones (also called *seed cones*) are modified branch systems. Each cone scale bears two **ovules**, or **megasporangia**, on its upper surface. Within each megasporangium, meiosis of a **megasporocyte**, or *megaspore mother cell*, produces four haploid **megaspores**. One of them divides mitotically, developing into the female gametophyte, which produces an egg within each of several archegonia. The other three megaspores are nonfunctional and soon degenerate.

When the ovule is ready to receive pollen, it produces a sticky droplet at the opening where the pollen grains land. **Pollination**, the transfer of pollen to the female cones, occurs in the spring for a week or ten days, after which the pollen cones wither and drop off the tree. One of the many pollen grains that adhere to the sticky female cone grows a **pollen tube**, an outgrowth that digests its way through the megasporangium to the egg within the archegonium. The germinated pollen grain with its pollen tube is the mature male gametophyte.

Ultimately, two nonmotile (non-flagellate) sperm cells form within the germinated pollen grain. When it reaches the female gametophyte, the pollen tube discharges the two sperm cells near the egg. One of these sperm cells fuses with the egg, in the process of **fertilization**, to form a zygote, or fertilized egg, which subsequently grows into a young pine embryo in the seed. The other sperm cell degenerates.

The developing embryo consists of an embryonic root and an embryonic shoot with several cotyledons (embryonic leaves). Haploid female gametophyte tissue surrounds the embryo and becomes the nutritive tissue in the mature pine seed. A tough, protective seed coat derived from the integuments encloses the embryo and nutritive tissue. The seed coat forms a thin, papery wing at one end that enables dispersal by air currents. Some seeds remain within the female cones for several years before being shed.

In the pine life cycle, the sporophyte generation is dominant, and the gametophyte generation is restricted in size to microscopic structures in the cones. Although the female gametophyte produces archegonia, the male gametophyte is so reduced that it does not produce antheridia. The gametophyte generation in pines, as in all seed plants, depends totally on the sporophyte generation for nourishment.

A major adaptation in the pine life cycle is elimination of the need for external water as a sperm transport medium. Instead, air currents carry pine pollen grains to female cones, and nonflagellate sperm cells move through a pollen tube to the egg. Pine and other conifers are plants whose reproduction is totally adapted for life on land.

Cycads have seed cones and compound leaves

Cycads (phylum Cycadophyta) were very important during the Triassic period, which began about 251 million years ago (mya) and is sometimes referred to as the “Age of Cycads.” Most cycad species are now extinct, and the few surviving ones, about 140 species, are tropical and subtropical plants

(a) A female Florida arrowroot (*Zamia integrifolia*) produces seed cones. This plant is the only cycad native to the United States. Like *Zamia*, most cycads are short plants, less than 2 m (6.5 ft) tall.

(b) This female cycad (*Encephalartos princeps*) native to South Africa bears three seed cones.

Figure 28-6 Cycads

with stout, trunklike stems and compound leaves that resemble those of palms or tree ferns (FIG. 28-6). Many cycads are endangered, primarily because they are popular as ornamentals and are gathered from the wild and sold to collectors. In the United States, cycads can be found in Florida, Texas, and California.

Cycad reproduction is similar to that in pines except that cycads are **dioecious** and therefore have seed cones on female plants and pollen cones on male plants. Their seed structure is most like that of the earliest seeds found in the fossil record. Cycads have also retained motile sperm cells, each of which has many hairlike flagella. Motile sperm cells are a vestige retained from the ancestors of cycads, in which sperm cells swam from antheridia to archegonia. In cycads specialized insects (almost exclusively beetles) carry pollen grains to the female plants and their cones. Following transfer to the female cone, the pollen grain germinates and grows a pollen tube. The sperm cells are released into this tube and swim to the egg.

***Ginkgo biloba* is the only living species in its phylum**

Ginkgo (phylum Ginkgophyta) is represented by a single *extant* (living) species, the maidenhair tree, *Ginkgo biloba* (FIG. 28-7). This native of eastern China grew in the wild in only two locations, although people had cultivated it for its edible seeds

female trees bear seeds whose fleshy outer coverings give off a foul odor that smells like rancid butter. In China and Japan, where people eat the seeds, the female trees are more common.

Ginkgo has been an important medicinal plant for centuries and is still a common herbal remedy today. Extracts from the leaves may enhance neurological functioning by increasing blood flow to the brain, although several recent studies have concluded that ginkgo does not improve memory or prevent dementia in elderly people. In 2013 scientists from the National Toxicology Program of the National Institutes of Health reported the development of cancers in rats and mice fed high doses of *Ginkgo biloba* extract.

(a) Close-up of a branch from a female ginkgo, showing the exposed seeds and the distinctive, fan-shaped leaves.

(b) Ginkgo (*Ginkgo biloba*) tree, exhibiting yellow fall foliage in the garden of the ancient Jinci Memorial Temple, China.

Figure 28-7 Ginkgo, or maidenhair tree

Gnetophytes include three unusual genera

The **gnetophytes** (nee' toe phites) (phylum Gnetophyta) consist of about 70 species in three diverse and obscure genera (*Gnetum*, *Ephedra*, and *Welwitschia*). Gnetophytes share certain features that make them unique among the gymnosperms. For example, gnetophytes have more efficient water-conducting cells, called *vessel elements*, in their xylem (see Chapter 33). Flowering plants also have vessel elements in their xylem, but of the gymnosperms, only the gnetophytes do. In addition, the cone clusters that some gnetophytes produce resemble flower clusters, and certain details in their life cycles resemble those of flowering plants. Despite these similarities, most botanists now think that gnetophytes represent evolutionary diversity in gymnosperms and are not in a direct line to flowering plants (see Fig. 28-2).

The genus *Gnetum* contains tropical vines, shrubs, and trees with broad leaves (FIG. 28-8a). Species in the genus *Ephedra* include many shrubs and vines that grow in deserts and other dry temperate and tropical regions. Some *Ephedra* species resemble horsetails in that they have jointed green stems with tiny leaves (FIG. 28-8b). Commonly called *joint fir*, *Ephedra* has been used medicinally for centuries. An Asiatic *Ephedra* is the source of ephedrine, which stimulates the heart and raises blood pressure. At one time, ephedrine was commonly sold over the counter in weight-control medications and herbal energy boosters; several deaths were reported from chronic use or overdose of products containing ephedrine, so its use has been restricted.

The third gnetophyte genus, *Welwitschia*, contains a single species found in deserts of southwestern Africa (FIG. 28-8c). Most of *Welwitschia*'s body—a long taproot—grows underground. Its short, wide stem forms a shallow disc, up to 0.9 m (3 ft) in diameter, from which two ribbonlike leaves extend. These two leaves continue to grow from the stem throughout the plant's life, but their ends are usually broken and torn by the wind, giving the appearance of numerous leaves. Each leaf grows to about 2 m (6.5 ft) in length. When *Welwitschia* reproduces, cones form around the edge of its disclike stem.

Dr. John D. Cunningham/Visuals Unlimited, Inc.

(a) The leaves of *Gnetum gnemon* resemble those of flowering plants. Note the exposed seeds. The species is native to southern Asia and the Maldives.

(c) *Welwitschia mirabilis* is native to deserts in southwestern Africa. It survives on moisture-laden fogs that drift inland from the ocean. Photographed in the Namib Desert, Namibia.

Figure 28-8 Gnetophytes

CHECKPOINT 28.2

- What is the dominant generation in the pine life cycle? How does pollination occur in gymnosperms?
- **CONNECT** What features distinguish gymnosperms from seedless plants?
- What are the four groups of gymnosperms?
- What features distinguish cycads from ginkgo? from gnetophytes?

28.3 Flowering Plants

LEARNING OBJECTIVES

- 5 Summarize the features that distinguish flowering plants from other plants.
- 6 Briefly explain the life cycle of a flowering plant and describe double fertilization.
- 7 Contrast monocots and eudicots, the two largest classes of flowering plants.
- 8 Discuss the evolutionary adaptations of flowering plants.

Flowering plants, or angiosperms (phylum Anthophyta), are the most successful plants today, surpassing even the gymnosperms in

importance. They have adapted to almost every habitat and, with at least 300,000 species, are Earth's dominant plants. Flowering plants come in a wide variety of sizes and forms, from herbaceous violets to massive eucalyptus trees. Some flowering plants—tulips and roses, for example—have large, conspicuous flowers; others, such as grasses and oaks, produce small, inconspicuous flowers.

Flowering plants are vascular plants that reproduce sexually by forming flowers and, following a unique double fertilization process, seeds within fruits. The fruit protects the developing seeds and often aids in their dispersal (see Chapter 37). Flowering plants have efficient water-conducting cells called **vessel elements** in their xylem and efficient sugar-conducting cells called **sieve tube elements** in their phloem (see Chapter 33).

Flowering plants are extremely important to humans because our survival as a species literally depends on them. All our major food crops are flowering plants; examples include rice, wheat, corn, potatoes, tomatoes, beans, apples, and citrus fruits. Woody flowering plants such as oak, cherry, and walnut provide valuable lumber. Flowering plants give us fibers, such as cotton and linen, and medicines, such as digitalis and codeine. Products as diverse as rubber, tobacco, coffee, chocolate, wine, and aromatic oils for perfumes come from flowering plants. *Economic botany* is the subdiscipline of botany that deals with plants of economic importance.

Monocots and eudicots are the two largest classes of flowering plants

Phylum Anthophyta is divided into several classes with only a few members each and two very large classes: the monocots (class Monocotyledones) and the eudicots (class Eudicotyledones). The smaller classes will be discussed later in this chapter in the context of their evolutionary significance. For now, we restrict our discussion of flowering plants to the monocots and eudicots, which collectively represent about

Table 28-2 Distinguishing Features of Monocots and Eudicots

Feature	Monocots	Eudicots
Flower parts	Usually in threes	Usually in fours or fives
Pollen grains	One furrow or pore	Three furrows or pores
Leaf venation	Usually parallel	Usually netted
Vascular bundles in stem cross section	Usually scattered or more complex arrangement	Arranged in a circle (ring)
Roots	Fibrous root system	Taproot system
Seeds	Embryo with one cotyledon	Embryo with two cotyledons
Secondary growth (wood and bark)	Absent	Often present

97% of all flowering plant species. Eudicots are more diverse and include many more species (at least 200,000) than the monocots (at least 90,000). **TABLE 28-2** provides a comparison of some of the general features of the two classes.

Monocots include palms, grasses, orchids, irises, onions, and lilies. Monocots are mostly herbaceous plants with long, narrow leaves that have parallel veins (the main leaf veins run parallel to one another). The parts of monocot flowers usually occur in threes (**FIG. 28-9a**). For example, a flower may have three sepals, three petals, six stamens, and a compound pistil consisting of three fused carpels (these flower parts are discussed shortly). Monocot seeds have a single **cotyledon**, or embryonic seed leaf; **endosperm**, a nutritive tissue, is usually present in the mature seed.

Eudicots include oaks, roses, mustards, cacti, blueberries, and sunflowers. Eudicots are either herbaceous (such as a tomato plant) or woody (such as a hickory tree). Their leaves vary in shape but usually are broader than monocot leaves, with netted (finely branched) veins. Flower parts usually occur in fours or fives or multiples thereof (**FIG. 28-9b**). Two cotyledons are present in eudicot seeds, and endosperm is usually absent in the mature seed, having been absorbed by the two cotyledons during seed development.

Figure 28-9 Flowering plants

Figure 28-10 Floral structure

This cutaway view of an *Arabidopsis* flower shows the details of basic floral structure. Each flower has four sepals (two are shown), four petals (two are shown), six stamens, and one long pistil. Four of the stamens are long, and two are short (two long and two short are shown). Pollen grains develop within sacs in the anthers. In *Arabidopsis*, the compound pistil consists of two carpels that each contain numerous ovules.

Sexual reproduction takes place in flowers

Flowers are reproductive shoots usually composed of four parts—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk, or **peduncle** (FIG. 28-10). The peduncle may terminate in a single flower or a cluster of flowers known as an **inflorescence**. The tip of the flower stalk that bears the flower parts is known as the **receptacle**.

All four floral parts are important in the reproductive process, but only the stamens (the “male” organs) and carpels (the “female” organs) produce gametes. A flower that has all four parts is a **complete flower**, whereas an **incomplete flower** lacks one or more of these four parts. A flower with both stamens and carpels is a **perfect flower**, whereas an **imperfect flower** has stamens or carpels, but not both.

Sepals, which make up the lowermost and outermost whorl on a floral shoot, are leaflike in appearance and often green (FIG. 28-11a). Sepals cover and protect the other flower parts when the flower is a bud. As the flower opens, the sepals fold back to reveal the more conspicuous petals. The collective term for all the sepals of a flower is the **calyx**.

The whorl just above the sepals consists of **petals**, which are broad, flat, and thin (like sepals and leaves) but vary in shape and are frequently brightly colored. Petals attract animal pollinators to the flower (see Chapter 37). Sometimes petals are fused to

form a tube (as in trumpet honeysuckle flowers) or other floral shape (as in snapdragons, whose petals form two lips). The petals of a flower are referred to collectively as the **corolla**.

Just inside the petals is a whorl of **stamens** (FIG. 28-11b). Each stamen is composed of a thin stalk, called a **filament**, and a saclike **anther**, where meiosis occurs to form microspores that develop into pollen grains. Each pollen grain produces two cells surrounded by a tough outer wall. One cell eventually divides to form two male gametes, or sperm cells, and the other produces a pollen tube through which the sperm cells travel to reach the ovule.

In the center of most flowers are one or more closed **carpels**, the “female” reproductive organs. Carpels bear ovules, which, as you may recall, are structures with the potential to develop into seeds. The carpels of a flower can be separate or fused into a single structure. The female part of the flower is also called a **pistil** (see Fig. 28-11b). A pistil may consist of a single carpel (a simple pistil) or a group of fused carpels (a compound pistil) (FIG. 28-12). Each pistil generally has three sections: a **stigma**, on which the pollen grain lands; a **style**, a necklike structure through which the pollen tube grows; and an **ovary**, an enlarged structure that contains one or more ovules. Each young ovule contains a female gametophyte that forms one female gamete (an egg), two *polar nuclei*, and several other haploid cells. After fertilization, the ovule develops into a seed, and the ovary develops into a fruit.

(a) The leaflike sepals of a rosebud (*Rosa*) enclose and protect the inner flower parts.

(b) A twinleaf (*Jeffersonia diphylla*) flower has eight yellow stamens. Note the simple pistil with its green ovary in the center of the flower.

Figure 28-11 Parts of a flower

The life cycle of flowering plants includes double fertilization

Flowering plants undergo alternation of generations in which the sporophyte generation is larger and nutritionally independent (FIG. 28-13). The gametophyte generation in flowering plants is microscopic and nutritionally dependent on the sporophyte. Flowering plants, like gymnosperms and certain other vascular plants, are heterosporous and produce two kinds of spores: microspores and megaspores. Sexual reproduction occurs in the flower.

Each young ovule within an ovary contains a megasporocyte (megaspore mother cell) that undergoes meiosis to produce four haploid megaspores. Three of them usually disintegrate, and one divides mitotically and develops into a mature female gametophyte, also called an **embryo sac**.

Embryo sacs in the vast majority of angiosperms contain seven cells with eight haploid nuclei. Six of these cells, including

(a) **Simple pistil.** This simple pistil consists of a single carpel.

(b) **Compound pistil.** This compound pistil has two united carpels. In most flowers with single pistils, the pistils are compound, consisting of two or more fused carpels.

Figure 28-12 Simple and compound pistils

the egg cell, contain a single nucleus each, and a central cell has two nuclei, called **polar nuclei**. The egg and the central cell with two polar nuclei are directly involved in fertilization; the other five cells in the embryo sac apparently have no direct role in the fertilization process and disintegrate. As the *synergids* (the two cells flanking the egg) disintegrate, however, they release chemicals that may affect the direction of pollen tube growth.

Each pollen sac, or microsporangium, of the anther contains numerous microsporocytes (microspore mother cells), each of which undergoes meiosis to form four haploid microspores. Every microspore develops into an immature male gametophyte, also called a *pollen grain*. Pollen grains are small, and each consists of two cells: the *tube cell* and the *generative cell*.

The anthers split open and begin to shed pollen. A variety of agents—including wind, water, insects, and other animal pollinators—transfer pollen grains to the stigma (see

Key Point

A significant feature of the flowering plant life cycle is **double fertilization**, in which one sperm cell unites with the egg, forming a zygote; the other sperm cell unites with the two polar nuclei, forming a triploid cell that gives rise to endosperm.

Figure 28-13 Life cycle of flowering plants

CONNECT Are microspores and megaspores haploid or diploid? Are they gametes? Explain your answer.

Chapter 37). If compatible with the stigma, the pollen grain germinates, and a pollen tube grows down the style and into the ovary. The germinated pollen grain with its pollen tube is the mature male gametophyte. Next, the generative cell divides to form two nonflagellate sperm cells. The sperm cells move down the pollen tube and are discharged into the embryo sac.

When the two sperm cells enter the embryo sac, *both* participate in fertilization. One sperm cell fuses with the egg, forming a zygote that divides by mitosis and develops into a multicellular embryo in the seed. The second sperm cell fuses with the two haploid polar nuclei of the central cell to

form a triploid (3n) cell that divides by mitosis and develops into **endosperm**, a nutrient tissue rich in lipids, proteins, and carbohydrates that nourishes the growing embryo. This fertilization process, which involves two separate nuclear fusions, is called **double fertilization** and is, with two exceptions, unique to flowering plants. (Double fertilization has been reported in the gymnosperms *Ephedra nevadensis* and *Gnetum gnemon*. This process differs from double fertilization in flowering plants in that an additional zygote, rather than endosperm, is produced. The second zygote later disintegrates.)

Seeds and fruits develop after fertilization

As a result of double fertilization and subsequent growth and development, each seed contains a young plant embryo and nutritive tissue (the endosperm), both of which are surrounded by a protective seed coat. In monocots, the endosperm persists and is the main source of food in the mature seed. In most eudicots, the endosperm nourishes the developing embryo, which subsequently stores food in its cotyledons.

As a seed develops from an ovule following fertilization, the ovary wall surrounding it enlarges dramatically and develops into a **fruit**. In some instances, other tissues associated with the ovary also enlarge to form the fruit (see discussion of fruits in Chapter 37). Fruits serve two purposes: to protect the developing seeds from desiccation as they grow and mature and to aid in the dispersal of seeds. For example, dandelion fruits have feathery plumes that are lifted and carried by air currents. Animals often assist in dispersing seeds found in edible fruits (FIG. 28-14). Once a seed lands in a suitable place, it may germinate and develop into a mature sporophyte that produces flowers, and the life cycle continues as described.

Flowering plants have many adaptations that account for their success

The evolutionary adaptations of flowering plants account for their success in terms of their ecological dominance and their great number of species. Seed production as the primary means of reproduction and dispersal, an adaptation shared with the gymnosperms, is clearly significant and provides a definite advantage over seedless vascular plants. Closed carpels, which give rise to fruits surrounding the seeds, and the process of double fertilization with its resulting endosperm increase the likelihood of reproductive success. The evolution of a variety of interdependencies with many types of insects, birds, and bats, which disperse pollen from one flower to another of the same species, is another reason for angiosperm success. Pollen transfer results in cross-fertilization, which mixes the genetic material and promotes genetic variation among the offspring.

Figure 28-14 Guava fruit and seeds

Animals eat fleshy fruits such as guava. The seeds are frequently swallowed whole and pass unharmed through the animals' digestive tracts.

Several distinctive features have contributed to the success of flowering plants in addition to their highly successful reproduction involving flowers, fruits, and seeds. Recall that most flowering plants have very efficient water-conducting vessel elements in their xylem, as well as tracheids. In contrast, the xylem of almost all seedless vascular plants and gymnosperms consists exclusively of tracheids. Most flowering plants also have efficient carbohydrate-conducting sieve tube elements in their phloem. Vascular plants other than flowering plants and gnetophytes lack vessel elements and sieve tube elements.

The leaves of flowering plants, with their broad, expanded blades, are very efficient at absorbing light for photosynthesis. Abscission (shedding) of these leaves during cold or dry periods reduces water loss and has enabled some flowering plants to expand into habitats that would otherwise be too harsh for survival. The stems and roots of flowering plants are often modified for food or water storage, another feature that helps flowering plants survive in severe environments.

Probably most crucial to the evolutionary success of flowering plants, however, is the overall adaptability of the sporophyte generation. As a group, flowering plants readily adapt to new habitats and changing environments. This adaptability is evident in the great diversity of growth forms exhibited by the various species of flowering plants. For example, the cactus is remarkably well-adapted to desert environments. Its stem stores water; its leaves (spines) have a reduced surface area available for transpiration (loss of water vapor; see Chapter 34) and may also protect against thirsty herbivorous animals; and its thick, waxy cuticle reduces water loss. In contrast, the water lily is well-adapted for wet environments, in part because it has air channels that provide adequate oxygen to stems and roots living in oxygen-deficient water and mud.

Floral structure provides insights into the evolutionary process

In evolution new structures or organs often originate by modification of previously existing structures or organs. (See Chapter 20 for the discussion of preadaptations.) Much evidence supports the classical interpretation that the four organs of a flower—sepals, petals, stamens, and carpels—arose from highly modified leaves. This evidence includes comparisons of the arrangement of vascular tissues in both flowers and leafy stems and of the developmental stages of floral parts and leaves.

Sepals are the most leaflike of the four floral organs, and botanists generally agree that sepals are specialized leaves. Although petals of many flowering plant species are leaflike in appearance, botanists generally view petals as modified stamens that later became sterile and leaflike. Cultivated roses and camellias provide evidence supporting this hypothesis; in some varieties the stamens have been transformed into petals, forming showy flowers with large numbers of petals.

The remarkably leaflike stamens and carpels of certain tropical trees and other species support the origin of stamens and

(a) The carpel resembles a folded leaf in which the ovules borne on its upper surface are enclosed.

(b) A cross section of the carpel, cut along the dashed line in (a).

Figure 28-15 Carpel of *Drimys piperita*

as floral organs fused or became reduced in size or number. These changes led to greater complexity in floral structure in some species and greater simplicity in other species. Interpreting the floral structures of so many different angiosperm species is sometimes difficult, but it is important because correct interpretations are essential to devising a phylogenetic classification scheme.

CHECKPOINT 28.3

- How do nonreproductive adaptations of flowering plants differ from those of gymnosperms?
- **CONNECT** How does the flowering plant life cycle differ from that of the gymnosperms?
- What are the two major classes of flowering plants, and how can one distinguish between them?
- **CONNECT** How does fertilization differ in gymnosperms and flowering plants?

carpels from leaves or leaflike organs. Consider, for example, the carpel of *Drimys*, a genus of flowering trees and shrubs native to Southeast Asia, Australia, and South America. This carpel resembles a leaf that is folded inward along the midrib, thereby enclosing the ovules, and joined along the entire length of the leaf's margin (FIG. 28-15).

The fundamental question is whether these leaf-like stamens and carpels are shared ancestral characters that were conserved (retained) during the course of evolution or instead are highly specialized organs (i.e., shared derived characters) that do not resemble early stamens and carpels. Many botanists who have studied this question have concluded that stamens and carpels are probably derived from leaves. Not all botanists accept the origin of stamens and carpels from highly modified leaves, however.

During the course of more than 130 million years of angiosperm evolution, floral structure diversified

28.4 The Evolution of Seed Plants

LEARNING OBJECTIVE

- 9 Summarize the evolution of gymnosperms from seedless vascular plants and trace the evolution of flowering plants from gymnosperms.

One group that descended from ancestral seedless vascular plants was the **progymnosperms**, all of which are now extinct. Progymnosperms had two derived features: leaves with branching veins (*megaphylls*) and woody tissue (*secondary xylem*) similar to that of modern gymnosperms. Progymnosperms, however, reproduced by spores, not seeds. *Archaeopteris*, a progymnosperm that lived about 370 mya, is one of the earliest known trees with “modern” woody tissue (FIG. 28-16a).

Fossils of several progymnosperms with reproductive structures intermediate between those of spore plants and seed plants have been discovered. For example, the evolution of microspores into pollen grains and of megasporangia into ovules (seed-producing structures) can be traced in fossil progymnosperms. Plants producing seeds appeared during the late Devonian period, more than 359 mya. The fossil record indicates that different groups of seed plants apparently arose independently several times.

As mentioned previously, fossilized remains of ginkgo are found in 200-million-year-old rocks, and other groups of gymnosperms were well established by 160 mya to 100 mya. Although the gymnosperms are an ancient group, some questions persist about the exact pathways of gymnosperm evolution. The fossil record indicates that progymnosperms probably gave rise to conifers and to another group of extinct plants called **seed ferns**, which were seed-bearing woody plants with fernlike leaves (FIG. 28-16b). The seed ferns, in turn, probably gave rise to cycads and ginkgo as well as to several gymnosperm groups now extinct. The origin of gnetophytes remains unclear, although molecular data indicate that they are closely related to conifers.

Our understanding of the evolution of flowering plants has made great progress in recent years

Flowering plants are the most recent clade of plants to evolve. The fossil record, although incomplete, suggests that flowering plants descended from gymnosperms. By the middle of the Jurassic period, about 180 mya, several gymnosperm lines existed with some features resembling those of flowering plants. Among other traits, these derived gymnosperms possessed leaves with broad, expanded blades and the first modified seed-bearing leaves, which nearly enclose the ovules. Beetles were evidently visiting these plants, and biologists have suggested that perhaps this relationship was the beginning of **coevolution**, a mutual adaptation between plants and their animal pollinators (see Chapter 37).

(a) Progymnosperm. *Archaeopteris*, which existed about 370 mya, had some features in common with modern seed plants but did not produce seeds.

(b) Seed fern. *Emlenopteris* produced seeds on fernlike leaves. Seed ferns existed from about 360 mya to 250 mya.

Figure 28-16 Evolution of seed plants

(a) Redrawn from Beck, C.B., "Reconstructions of *Archaeopteris* and Further Consideration of Its Phylogenetic Position," *American Journal of Botany*, Vol. 49 (1962); **(b)** Redrawn from Andrews, H.N., *Ancient Plants and the World They Lived In* (Comstock, New York, 1947).

One important task facing paleobotanists (biologists who study fossil plants) is determining which of the ancient gymnosperms are in the direct line of evolution leading to the flowering plants. Given the structural data, most botanists hypothesize that flowering plants arose only once; that is, they think that there is only one line of evolution from the gymnosperms to the flowering plants.

Based largely on structural data, many evolutionary botanists previously thought that the gnetophytes were the gymnosperm clade most closely related to flowering plants. However, new hypotheses of angiosperm origin have been proposed in recent years with advances in molecular comparisons, genetic studies (particularly as gene function relates to reproductive development), and additional fossil discoveries. Currently, many botanists think that the closest extant gymnosperms related to flowering plants are probably conifers, but this hypothesis is far from certain, and the origin and early evolution of flowering plants continue to challenge botanists.

The oldest definitive trace of flowering plants in the fossil record consists of ovules enclosed in tiny podlike fruits interpreted as carpels in Jurassic and Lower Cretaceous rocks some 125 million to 145 million years old (**FIG. 28-17a**). The oldest fossilized flowers are about 118 million to 120 million years old.

(a) The oldest known fossil angiosperm. This fossil of *Archaeofructus* shows a carpel-bearing stem. Discovered in northeastern China, it is about 125 million years old.

(b) Fossil flower. The fossilized flower of the extinct plant *Archaeanthus linnenbergeri*, which lived about 100 mya. The scars on the reproductive axis (receptacle) may show where stamens, petals, and sepals were originally attached but abscised (fell off). Many spirally arranged pistils were still attached at the time this flower was fossilized.

Figure 28-17 Fossil angiosperms

Key Point

Flowering plants evolved from ancient gymnosperms. Basal angiosperms are early diverging clades that still survive today.

(a) One hypothesis of relationships among the flowering plants, based on fossil and molecular evidence. *Amborella*, water lilies, and star anise are living plants whose ancestors apparently branched off of the angiosperm family tree early. These early clades were followed by the magnoliids, the monocots, and the eudicots.

Figure 28-18 Evolution of flowering plants

CONNECT According to the cladogram, do all basal angiosperms possess vessel elements?

By 90 mya, during the Cretaceous period, flowering plants had diversified and had begun to replace gymnosperms as Earth's dominant plants. Fossils of flowering plant leaves, stems, flowers, fruits, and seeds are numerous and diverse. They outnumber fossils of gymnosperms and ferns in Late Cretaceous deposits, indicating the rapid success of flowering plants once they appeared (FIG. 28-17b). Many angiosperm species apparently arose from changes in chromosome number. (See discussion of allopolyploidy and sympatric evolution in Chapter 20.)

The basal angiosperms comprise three clades

Beginning in 1999, a series of cladistic analyses of structural features and molecular comparisons have helped clarify relationships among the angiosperm classes. In the process many long-held assumptions about early angiosperm lineages have been discarded. The evidence indicates that several clades of basal (early-diverging) angiosperms evolved before the divergence of core angiosperms (FIG. 28-18a). The 170 species of

Key Experiment

Plants commonly known as hydatellas were incorrectly classified as grasses until recent molecular evidence indicated that they are basal angiosperms closely related to water lilies. Do these plants have any reproductive features that may indicate that they are one of the most ancient surviving lineages of angiosperms?

EXPERIMENT: *Trithuria inconspicua* (formerly *Hydatella inconspicua*), a small aquatic plant, was collected at a lake in Northland, New Zealand, and its embryo sacs were carefully analyzed.

© Justin Goh, School of Biological Sciences, University of Auckland, Auckland, New Zealand

RESULTS AND CONCLUSION: As in gymnosperms, the mother plant turns over nutrients to the seed *before* fertilization has occurred. This gymnosperm-like reproductive feature may represent a shared ancestral character that was retained during the transition from gymnosperms to flowering plants, thus supporting the view that hydatellas are representative of an ancient angiosperm lineage. Alternatively, this feature may represent a shared derived character not found in earlier hydatella ancestors.

SOURCE: Friedman, W.E., "Hydatellaceae Are Water Lilies with Gymnospermous Tendencies," *Nature*, Vol. 453 (May 1, 2008).

Figure 28-19 The basal angiosperm *Trithuria*

Trithuria inconspicua belongs to an ancient clade that consists of about 10 species native to Australia, New Zealand, and India.

CONNECT How is the nutritive tissue in the seeds of gymnosperms formed?

basal angiosperms represent groups thought to be ancestral to all other flowering plants.

The oldest surviving clade of basal angiosperms is represented by a single extant species, *Amborella trichopoda* (FIG. 28-18b). A shrub native to New Caledonia, an island in the South Pacific, *Amborella* may be the nearest living relative to the ancestor of all flowering plants. The water lilies and related families compose the second clade of basal angiosperms (FIG. 28-18c and FIG. 28-19). This clade, which contains about 70 species of aquatic or wetland herbs, may be the second-oldest surviving lineage. Star anise and relatives—the third clade of basal angiosperms—consist of about 100 species of vines, trees, and shrubs found mostly in warmer climates. Star anise is important economically because it is a source of spice used by confectioners and anise oil (FIG. 28-18d). Star anise is also used to make Tamiflu, a treatment for influenza.

The core angiosperms comprise magnoliids, monocots, and eudicots

Most angiosperm species belong to a clade of **core angiosperms**, which is divided into three subclades: magnoliids, monocots, and eudicots. **Magnoliids** include species in the magnolia, laurel, and black pepper families as well as several related families (FIG. 28-18e). Although magnoliids were traditionally classified with the eudicots as “dicots,” molecular evidence such as DNA sequence comparisons indicates that the magnoliids are neither eudicots nor monocots. Native to tropical or warm temperate regions, magnoliids include several economically important plants, such as avocado, black pepper, nutmeg, and bay laurel.

CHECKPOINT 28.4

- What features distinguish progymnosperms from seed ferns?
- Describe the significant features of the oldest known fossil angiosperm.
- Are monocots considered basal or core angiosperms? Explain your answer.

Summary: Focus on Learning Objectives

28.1 An Introduction to Seed Plants (page 585)

1 Compare the features of gymnosperms and angiosperms.

- The two groups of seed plants are the **gymnosperms** and the **angiosperms**. Gymnosperms produce seeds that are totally exposed or borne on the scales of cones; an ovary wall does not surround the ovules of gymnosperms. Angiosperms are flowering plants that produce their seeds within a fruit (a mature ovary).

28.2 Gymnosperms (page 586)

2 Trace the steps in the life cycle of a pine and compare its sporophyte and gametophyte generations.

- A pine tree is a mature sporophyte; pine gametophytes are extremely small and nutritionally dependent on the sporophyte generation. Pine is heterosporous and produces microspores and megaspores in separate cones.
- Male cones produce **microspores** that develop into **pollen grains** (immature male gametophytes) that are carried by air currents to female cones.
- Female cones produce **megaspores**. One of each four megaspores produced by meiosis develops into a female gametophyte within an **ovule** (**megasporangium**).
- After **pollination**, the transfer of pollen to the female cones, a **pollen tube** grows through the megasporangium to the egg within the archegonium. After **fertilization**, the zygote develops into an embryo encased inside a seed adapted for wind dispersal.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns.

- Unlike bryophytes, gymnosperms are vascular plants. Unlike bryophytes and ferns, gymnosperms produce seeds. Gymnosperms also produce wind-borne pollen grains, a feature absent in ferns and other seedless vascular plants.

4 Name and briefly describe the four phyla of gymnosperms.

- Conifers** (phylum Coniferophyta), the largest phylum of gymnosperms, are woody plants that bear *needles* (slender leaves that are usually evergreen) and produce seeds in cones. Most conifers are **monoecious** and have male and female reproductive parts in separate cones on the same plant.
- Cycads** (phylum Cycadophyta) are palmlike or fernlike in appearance. They are **dioecious**—they have male and female reproductive structures on separate plants—but reproduce with pollen and seeds in conelike structures.
- Ginkgo biloba*, the only surviving species in phylum Ginkgophyta, is a deciduous, dioecious tree. The female **ginkgo** produces fleshy seeds directly on branches.
- Gnetophytes** (phylum Gnetophyta) are an obscure clade of gymnosperms that has a few traits associated with angiosperms.

28.3 Flowering Plants (page 591)

5 Summarize the features that distinguish flowering plants from other plants.

- Flowering plants**, or angiosperms (phylum Anthophyta), constitute the phylum of vascular plants that produce flowers and seeds enclosed within a **fruit**. They are the most diverse and most successful group of plants.

- The flower, which may contain **sepals**, **petals**, **stamens**, and **carpels**, functions in sexual reproduction. Unlike those of gymnosperms, the ovules of flowering plants are enclosed within an **ovary**. After fertilization, the ovules become seeds, and the ovary develops into a fruit.

6 Briefly explain the life cycle of a flowering plant and describe double fertilization.

- The sporophyte generation is dominant in flowering plants; gametophytes are extremely reduced in size and nutritionally dependent on the sporophyte generation. Flowering plants are heterosporous and produce microspores and megaspores within the flower.
- Each microspore develops into a pollen grain (immature male gametophyte). One of each four megaspores produced by meiosis develops into an **embryo sac** (female gametophyte). Within the embryo sac, the egg cell and the central cell with two **polar nuclei** participate in fertilization.
- Double fertilization**, which results in the formation of a diploid zygote and triploid **endosperm**, is characteristic of flowering plants.

7 Contrast monocots and eudicots, the two largest classes of flowering plants.

- Most **monocots** (class Monocotyledones) have floral parts in threes, and their seeds each contain one **cotyledon**. The nutritive tissue in their mature seeds is endosperm.
- Eudicots** (class Eudicotyledones) usually have floral parts in fours or fives or multiples thereof, and their seeds each contain two cotyledons. The nutritive organs in their mature seeds are usually the cotyledons, which have absorbed the nutrients in the endosperm.

8 Discuss the evolutionary adaptations of flowering plants.

- Flowering plants reproduce sexually by forming flowers. After double fertilization, seeds form within fruits. Flowering plants have efficient water-conducting **vessel elements** in their xylem and efficient carbohydrate-conducting **sieve tube elements** in their phloem. Wind, water, insects, or other animals transfer pollen grains in various flowering plants.

28.4 The Evolution of Seed Plants (page 597)

9 Summarize the evolution of gymnosperms from seedless vascular plants and trace the evolution of flowering plants from gymnosperms.

- Seed plants arose from seedless vascular plants. **Progymnosperms** were seedless vascular plants that had megaphylls and “modern” woody tissue. Progymnosperms probably gave rise to conifers as well as to **seed ferns**, which in turn likely gave rise to cycads and ginkgo.
- The evolution of the gnetophytes is unclear, although molecular data indicate that they are closely related to conifers.
- Flowering plants probably descended from ancient gymnosperms that had specialized features, such as leaves with broad, expanded blades and closed carpels. Flowering plants likely arose only once; that is, there is only one line of evolution from the gymnosperms to the flowering plants.

Test Your Understanding

Know and Comprehend

1. Seed plants *lack* which of the following structure(s)?
(a) ovules surrounded by integuments (b) microspores and megaspores (c) vascular tissues (d) a large, nutritionally independent sporophyte (e) a large, nutritionally independent gametophyte
2. Conifers, cycads, ginkgo, and gnetophytes are collectively called (a) club mosses (b) gymnosperms (c) angiosperms (d) eudicots (e) seedless vascular plants
3. The immature male gametophytes of pine are called (a) ovules (b) stamens (c) seed cones (d) pollen grains (e) polar nuclei
4. The transfer of pollen grains from the male to the female reproductive structure is known as (a) pollination (b) fertilization (c) embryo sac development (d) seed development (e) fruit development
5. Motile sperm cells are found as vestiges in these two gymnosperm groups: (a) monocots, eudicots (b) gnetophytes, conifers (c) gnetophytes, flowering plants (d) cycads, conifers (e) cycads, ginkgo
6. There are at least _____ species of flowering plants worldwide. (a) 300 (b) 3000 (c) 30,000 (d) 300,000 (e) 3,000,000
7. A simple pistil consists of a single (a) calyx (b) carpel (c) ovule (d) filament (e) petal
8. A flower that lacks stamens is both _____ and _____. (a) complete; imperfect (b) incomplete; perfect (c) complete; perfect (d) incomplete; imperfect
9. After fertilization, the _____ develop(s) into a fruit and the _____ develop(s) into a seed.
(a) ovary; ovule (b) polar nuclei; ovule (c) ovary; endosperm (d) ovule; ovary (e) ovule; polar nuclei
10. The female gametophyte in flowering plants is also called the (a) polar nuclei (b) anther (c) embryo sac (d) endosperm (e) sporophyll
11. This flowering plant may be the nearest living relative to the ancestor of all flowering plants. (a) *Amborella* (b) *Archaeopteris* (c) *Gnetum* (d) water lily (e) magnolia

Apply and Analyze

12.  This cross section through an ovary reveals that the pistil is (a) simple, with one carpel (b) compound, with two fused carpels (c) compound, with three fused carpels (d) compound, with six separate carpels (e) compound, with six fused carpels

13. You are given a plant that you have never seen before (see figure). Is it a gymnosperm or angiosperm? A monocot or eudicot? What are the features that helped you make these determinations?

14. **VISUALIZE** Sketch a seed of a gymnosperm and of a monocot. Label the embryo, seed coat, and nutritive tissue (giving its specific name). Indicate the ploidy of each structure (haploid, diploid, or triploid).
15. **CONNECT** How do the life cycles of seedless plants (see Chapter 27) and seed plants differ? In what fundamental ways are they alike?

Evaluate and Synthesize

16. **EVOLUTION LINK** Most flowers contain both male and female reproductive structures, in contrast to the cones of gymnosperms, which are either male or female. Explain how bisexual flowers might be an advantageous evolutionary adaptation to the flowering plants that possess them.
17. **EVOLUTION LINK** Contrast the algae, mosses, ferns, gymnosperms, and angiosperms with respect to their dependence on water as a transport medium for reproductive cells. Suggest a hypothesis to explain how the differences might be adaptive to living on land.
18. **EVOLUTION LINK** Where would you place the progymnosperms on Figure 28-2? Explain your reasoning.

29 The Fungi

Mushrooms, morels, and truffles, delights of the gourmet, share a recent common ancestry with baker's yeast, the black mold that forms on stale bread, and the mildew that collects on damp shower curtains. The science of **mycology**, the study of fungi, is concerned with all these diverse life-forms. Mycologists have described about 100,000 species, most of which are terrestrial, but they estimate that there are more than 1.5 million species. Biologists who use the kingdom as a taxon group these organisms in kingdom Fungi, one of the eukaryotic kingdoms.

Fungi grow best in moist habitats, but they are found universally wherever organic material is available. They require moisture to grow, and they can obtain water from a humid atmosphere as well as from the medium on which they live. When the environment becomes dry, fungi survive by going into a resting stage or by producing spores (see photograph) that resist desiccation (drying out).

Some fungi grow to enormous size. In Washington State a fungal clone (*Armillaria ostoyae*) has been identified that covers more than 1500 acres. This giant fungus, which is mainly underground, developed from a single spore that germinated more than a thousand years ago. The fungus has fragmented and is no longer one continuous body.

Like prokaryotes, most fungi are decomposers that obtain nutrients and energy from dead organic matter. They are vital members of ecosystems because they break down the organic compounds found in dead organisms, leaves, garbage, sewage, and other waste. When they decompose organic compounds, carbon and other elements are released into the environment, where they are recycled.

Many fungi form vital symbiotic associations. For example, most terrestrial plants have fungal partners that live in close association with their roots. The fungi help the plants obtain phosphate ions and other needed minerals from the soil. In exchange, the plants provide the

KEY CONCEPTS

- 29.1** Fungi are eukaryotic heterotrophs that absorb nutrients from their surroundings; most grow as multicellular filaments called hyphae that form a tangled mass called a mycelium.
- 29.2** Most fungi have complex life cycles and reproduce both asexually and sexually by means of spores.
- 29.3** According to current hypotheses, fungi evolved from a unicellular, flagellate protist and diverged into several groups.
- 29.4** Fungi are of major ecological importance; they are decomposers, and they form symbiotic relationships with other organisms.
- 29.5** Fungi are of major economic, biological, and medical importance.

PHOTO: Fungal spores. These collared earthstars (*Geastrum triplex*) are releasing puffs of microscopic spores after their sacs, which are about 1.3 cm (0.5 in.) wide, were hit by raindrops. This fungus is common in leaf litter under trees throughout North America.

imageBROKER/Alamy Stock Photo

fungi with organic nutrients. Some fungi live symbiotically with algae and cyanobacteria as lichens. Others are parasites and pathogens that cause disease in animals or plants.

29.1 Characteristics of Fungi

LEARNING OBJECTIVES

- 1 Describe the distinguishing characteristics of fungi.
- 2 Describe the body plan of a fungus.

All **fungi** (sing., *fungus*) are eukaryotes; their cells contain membrane-enclosed nuclei, mitochondria, and other membranous organelles. Although they vary strikingly in size and shape, fungi share certain key characters, including their way of obtaining nutrition.

The optimum pH for most fungal species is about 5.6, but various fungi can tolerate and grow in environments where the pH ranges from 2 to 9. Many fungi are less sensitive to high osmotic pressures than are bacteria. As a result, they can grow in concentrated salt solutions or in sugar solutions such as jelly, which discourage or prevent bacterial growth. Fungi also thrive over a wide temperature range. Even refrigerated food may be invaded by fungi.

Fungi absorb food from the environment

Like animals, fungi are heterotrophs. For their nutritional and energy needs, they depend on preformed carbon molecules produced by other organisms. However, fungi do not ingest food and then digest it in the body as animals do. Instead, they infiltrate a food source and secrete digestive enzymes onto it. Digestion takes place outside the body. When complex molecules are broken down into smaller compounds, the fungus absorbs the predigested food into its body.

The fungus is very efficient at absorbing nutrients and growing. It rapidly converts nutrients into new cell material. If excessive amounts of nutrients are available, fungi store them, usually as lipid droplets or glycogen.

Fungi have cell walls that contain chitin

Like the cells of bacteria, certain protists, and plants, fungal cells are enclosed by cell walls during at least some stage in their life cycle. Fungal cell walls, however, have a different chemical composition from cell walls of other organisms. In most fungi the cell wall consists of complex carbohydrates, including **chitin**, a polymer that consists of subunits of a nitrogen-containing sugar (see Fig. 3-11). Chitin is also a component of the external skeletons of insects and other arthropods. It is resistant to breakdown by most microorganisms.

Most fungi consist of a network of filaments

The simplest fungi are the **yeasts**, which are unicellular, with a round or oval shape. Yeasts are widely distributed in the soil; on leaves, fruits, and cured meats; and on and in our bodies. The importance of some yeasts in medicine, biological research, and the food industry is discussed later in this chapter.

Most fungi are multicellular. The body consists of long, branched, threadlike filaments called **hyphae** (sing., *hypha*) (FIGS. 29-1a and b). Hyphae consist of tubular cell walls surrounding the plasma membranes of the fungal cells. They are an adaptation to the fungal mode of nutrition. Growth occurs at the tips of the hyphae; as the hyphae elongate, the fungus grows into and infiltrates food sources. The fungus absorbs nutrients through its very large surface area.

Figure 29-1 Fungus body plan

Spores carried by the air settle on food. They germinate and produce a mass of threadlike filaments called hyphae. The hyphae penetrate the food to obtain nourishment and produce a mass of hyphae called the mycelium. Eventually, specialized hyphae grow from the mycelium, giving rise to erect stalks with fruiting bodies (sporangia) at their tops. When the walls of the sporangia rupture, new spores are released into the air.

As hyphae grow they form a tangled mass or tissuelike network, called a **mycelium** (pl., *mycelia*). Fungi that form mycelia are commonly called *molds*. The cobweb-like mold sometimes seen on bread is the mycelium of a fungus. What is not seen is the extensive mycelium that grows into the bread. Depending on environmental conditions, some fungi can alternate between a yeast phase and a phase in which they produce hyphae.

In most fungi hyphae are divided by cross walls, called **septa** (sing., *septum*), into individual cells containing one or more nuclei (FIGS. 29-1c and d). As we will discuss, the presence of septa is an important character in the two largest fungal phyla (which include the most complex fungi). The septa of many fungi are perforated by a pore that may be large enough to permit organelles to flow from cell to cell. Some fungi are **coenocytes**, which lack septa. In these species nuclear division is not followed by cytoplasmic division. As a result, a coenocytic fungus is one elongated, multinucleated, giant cell (FIG. 29-1e).

CHECKPOINT 29.1

- **CONNECT** What characters distinguish fungi from other organisms?
- How does the body of a yeast differ from that of a mold?

29.2 Fungal Reproduction

LEARNING OBJECTIVE

- 3 Describe the life cycle of a typical fungus, including sexual and asexual reproduction.

Most fungi reproduce by means of microscopic **spores**, reproductive cells that can develop into new organisms. In most groups spores are nonmotile. They are dispersed by wind, water, or animals. The air we breathe is filled with hundreds of thousands of fungal spores. When a spore germinates, it gives rise to a hypha, which then develops into a mycelium (FIG. 29-2).

Figure 29-2 Germination of a spore to form a mycelium

Fungi produce spores either sexually or asexually. With asexual reproduction new individuals are produced quickly, but there is little genetic variability. Sexual reproduction involves meiosis and generates new genotypes.

Spores are usually produced on specialized aerial hyphae or in fruiting structures. When positioned up above the ground, spores can be easily dispersed. Structures in which spores are produced are called **sporangia** (sing., *sporangium*). The aerial hyphae of some fungi produce spores in large, complex reproductive structures, referred to as **fruiting bodies**. The familiar part of a mushroom is a large fruiting body. We do not normally see the bulk of the fungus, a nearly invisible mycelium buried out of sight in the rotting material or soil on which it grows.

Many fungi reproduce asexually

Yeasts reproduce asexually, primarily by forming buds that pinch off from the parent cell (FIG. 29-3). Many species of multicellular fungi also reproduce asexually. Spores are produced by mitosis and then released into the air or water. **Conidiophores** (from the Greek, meaning “dust-bearers”) are specialized hyphae that produce asexual spores called **conidia** (sing., *conidium*). The arrangement of conidia on conidiophores varies from species to species.

Most fungi reproduce sexually

Fungi are a diverse group with many variations in their life cycles. Most fungi (but not all) reproduce both asexually and sexually. FIGURE 29-4 illustrates a generalized life cycle. Many fungal species reproduce sexually when they come into

(a) Yeasts can reproduce asexually by budding.

(b) Color enhanced SEM of *Saccharomyces cerevisiae*. Note that several yeast cells are budding, a form of asexual reproduction. Also known as baker's or brewer's yeast, this fungus can ferment sugar, producing carbon dioxide and alcohol.

Figure 29-3 Yeasts are unicellular fungi

Most fungi can reproduce both asexually (which allows rapid proliferation) and sexually (which produces new genotypes).

Figure 29-4 The basic sequence of events in most fungal life cycles

CONNECT Beadle and Tatum used asexual spores of the fungus *Neurospora* in their experiments described in Figure 13-2. How did they obtain strains that differed in their nutritional requirements, given that asexual spores derived from the same parent are expected to be genetically identical?

contact with other mating types. In contrast to the majority of animal and plant cells, most fungal cells contain haploid nuclei. In sexual reproduction the hyphae of two genetically compatible mating types come together, and their cytoplasm fuses, a process called **plasmogamy**. The resulting cell has two

haploid nuclei, one from each fungus. This cell gives rise by mitosis to other cells with two nuclei. At some point the two haploid nuclei fuse. This process, called **karyogamy**, results in a cell containing a diploid nucleus known as a **zygote nucleus**. In some groups the zygote nucleus is the only diploid nucleus.

In the two largest fungal phyla, the ascomycetes and basidiomycetes (discussed later in this chapter), plasmogamy occurs (hyphae fuse), but karyogamy (fusion of the two different nuclei) does not follow immediately. For a time, the nuclei remain separate within the fungal cytoplasm. Hyphae that contain two genetically distinct, sexually compatible nuclei within each cell are described as **dikaryotic** (see Fig. 29-1d). This condition is referred to as $n + n$ rather than $2n$ because there are two separate haploid nuclei. Hyphae that contain only one nucleus per cell are described as **monokaryotic**. The presence of a dikaryotic stage is an important defining character of the ascomycetes and basidiomycetes.

Fungi communicate chemically by secreting signaling molecules called **pheromones**. At least one pheromone has been identified in each major fungal group. The pheromone binds with a compatible receptor on a different mating type. For example, in the zygomycetes, a pheromone induces the formation of specialized aerial hyphae. Another pheromone causes the tips of aerial hyphae of opposite mating types to grow toward each other and fuse prior to sexual reproduction.

CHECKPOINT 29.2

- **CONNECT** How is a diploid cell different from a dikaryotic cell?
- **VISUALIZE** Draw a generalized life cycle of a fungus. Include asexual and sexual reproduction as well as haploid, diploid, and dikaryotic stages.

29.3 Fungal Diversity

LEARNING OBJECTIVES

- 4 Give arguments to support the hypothesis that fungi are opisthokonts, more closely related to animals than to plants.
- 5 Give arguments to support the hypothesis that chytrids may have been the earliest fungal group to evolve from the most recent common ancestor of fungi.
- 6 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.

For centuries biologists classified fungi in the plant kingdom. Like plants, fungi have cell walls and vacuoles and are sessile; that is, they cannot move around from place to place. Also, like plants, many types of fungi inhabit the soil. However, systematists began to question this classification, and in 1969, R.H. Whittaker proposed that fungi be assigned to a separate kingdom, Fungi.

Unlike plants, fungal cell walls do not contain cellulose. Rather, they contain chitin, a polysaccharide found in insect skeletons. The fungal mode of nutrition is also very different from that of plants. Unlike plants, fungi cannot produce their own organic materials from a simple carbon source (carbon dioxide). Like animals, fungi are heterotrophs.

As with systematics for other kingdoms, fungal systematics is a challenging and continuously changing process. For example, slime molds and water molds were formerly classified as fungi but are now included among the protists (see Chapter 26).

Fungi are assigned to the opisthokont clade

Systematists hypothesize that the common ancestor of all plants, fungi, and animals was an ancient flagellate protist. As discussed in Chapter 26, amoebzoa (a group of amoebas), fungi, animals, and a few protists, including the choanoflagellates (a group of flagellate protists), form a monophyletic “supergroup,” the **unikonts**. Within this supergroup, the clade **opisthokonts** includes the choanoflagellates, the animals, and the fungi. Both genetic and structural similarities support this grouping. Like animals, fungi have platelike cristae in their mitochondria. Another key character shared by members of this clade is that flagellate cells propel themselves with a single posterior flagellum. In other eukaryote groups, flagellate cells move by means of one or more anterior flagella. Based on structural characters and on molecular data, systematists now view fungi as more closely related to animals than to plants.

Diverse groups of fungi have evolved

Fossil evidence has not been very helpful to systematists studying evolutionary relationships among fungal groups. Most fossilized fungi recovered to date have been microscopic. For example, fossilized fungal spores have been found in amber more than 225 million years old, and fossils of hyphae associated with cyanobacteria or algae have been dated as more than 550 million years old. Few large fungal fossils, such as mushrooms, have been found.

Historically, fungi have been classified mainly on the characteristics of their sexual spores and fruiting bodies. More recently, molecular data, such as comparative DNA and RNA sequences, have helped clarify relationships among fungal groups. Currently, many mycologists assign fungi to five main groups: Chytridiomycota, Zygomycota, Glomeromycota, Ascomycota, and Basidiomycota (FIG. 29-5 and TABLE 29-1). Some biologists consider each of these groups to be a phylum. However, some of these groups are not monophyletic (see Chapter 23), and mycologists are in the process of assigning fungi to additional clades.

In this edition of *Biology*, we will discuss fungi in the five phyla shown in Figure 29-5 and listed in Table 29-1. Microsporidia, a group of intracellular parasites, are classified in this text with the zygomycetes, although in the future they may be assigned to their own taxon. About 95% of all named fungi have been assigned to phyla Ascomycota and Basidiomycota. These phyla are considered *sister taxa* because they share a more recent common ancestor with each other than either does with any other group. Fungi of phyla Ascomycota and Basidiomycota have septate hyphae and a dikaryotic stage during the sexual part of their life cycle.

Until recently, mycologists had assigned about 25,000 species of fungi that did not fit into the major groups to a group called deuteromycetes (phylum Deuteromycota). It was a polyphyletic group (members did not share a recent common

Figure 29-5 Cladogram of currently recognized groups of fungi

This cladogram shows phylogenetic relationships among living fungi, based on comparisons of ribosomal and nuclear gene sequence data for many species. The chytrids were the lineage that branched off first during fungal evolution. Note that ascomycetes and basidiomycetes are sister clades. Remember that the phylogeny of fungi is a work in process.

ancestor) lumped together simply as a matter of convenience. Mycologists classified fungi as deuteromycetes if no sexual stage had been observed for them at any point during their life cycle. Some of these fungi have lost the ability to reproduce sexually, whereas others reproduce sexually only rarely. Most fungi classified as deuteromycetes reproduce only by means of asexual spores. Mycologists have identified relationships between

deuteromycetes and their sexually reproducing relatives, based on DNA comparisons among various species. Most of the deuteromycetes have been reassigned to phylum Ascomycota, and a few have been reassigned to phylum Basidiomycota. (By convention, the asexual stage is still identified as a deuteromycete.)

Chytrids have flagellate spores

At one time, biologists considered the **chytrids**, also known as **chytridiomycetes** (phylum Chytridiomycota), to be funguslike protists, similar in many respects to the water molds. However, both structural and molecular characters indicate that the approximately 1000 species of chytridiomycetes are members of kingdom Fungi. Like fungi, their cell walls contain chitin, and molecular comparisons—particularly of DNA and RNA sequences—have provided compelling evidence that chytrids are indeed fungi. However, recent comparisons of rRNA sequences suggest that chytrids are not a monophyletic group, and they may be divided into four clades.

Chytrids are small, relatively simple fungi that inhabit ponds and damp soil. A few species have been found in salt water. Most chytrids are decomposers that degrade organic matter. However, a few species cause disease in plants and animals. A parasitic chytrid has been partly responsible for declining amphibian populations. Infected frogs have been identified in many parts of the world (see *Inquiring About: Declining Amphibian Populations*, in Chapter 57).

Most chytrids are unicellular or composed of a few cells that form a simple body, called a **thallus**. The term *thallus* describes the simple body plan of certain algae, fungi, and plants. The thallus may have slender extensions, called *rhizoids*, that anchor it to a food source and absorb food (FIG. 29-6). Chytrids are the only fungi that have flagellate cells. Their spores bear a single, posterior flagellum. Sexual reproduction has not been identified in most chytrids. Species that do reproduce sexually have flagellate gametes.

Table 29-1 Characteristics of Currently Recognized Phyla of Fungi

	Phylum and Common Types	Asexual Reproduction	Sexual Reproduction	Other Key Characters
	Chytridiomycota (chytrids or chytridiomycetes) <i>Allomyces</i>	Flagellate, diploid zoospores produced by mitosis in zoosporangia	Flagellate, haploid gametes in some species	Haploid zoospores produced in resting sporangia; form haploid thallus
	Zygomycota (zygomycetes) Black bread mold Microsporidia are classified with the zygomycetes.	Haploid spores produced in sporangia	Zygospores develop in zygosporangia.	Important decomposers; some are insect parasites. Microsporidia are opportunistic pathogens that infect animals.
	Glomeromycota (glomeromycetes)	Large, multinucleate blastospores	Has not been observed	Form arbuscular mycorrhizae with plant roots
	Ascomycota (ascomycetes) Yeasts, powdery mildews, molds, morels, truffles	Conidia pinch off from conidiophores.	Ascospores develop in asci.	Have a dikaryotic stage; form important symbiotic relationships as lichens and mycorrhizae
	Basidiomycota (basidiomycetes or club fungi) Mushrooms, bracket fungi, puffballs, rusts, smuts	Uncommon	Basidiospores develop on club-shaped basidia.	Have a dikaryotic stage; many form mycorrhizae with tree roots

Figure 29-6 Chytrid

Nomarski differential interference micrograph of a common chytrid (*Chytridium conervae*). Many chytrids have a microscopic body form consisting of a rounded, coenocytic thallus and branched rhizoids that superficially resemble roots. The rhizoids may anchor the chytrid thallus and absorb predigested food.

Some chytrids produce branched, coenocytic mycelia. *Allomyces*, a large, common chytrid, has an unusual life cycle compared with that of most fungi. It undergoes an **alternation of generations** (common in plants, but rare in fungi), spending part of its life as a multicellular haploid (n) thallus and part as a multicellular diploid ($2n$) thallus (FIG. 29-7). The haploid and diploid thalli are similar in appearance. At the tips of its branches, the haploid thallus bears two types of sporangia, structures in which gametes form by mitosis. Each sporangium produces a different type of flagellate gamete.

Each type of gamete secretes a pheromone that attracts the other type. The two gametes fuse, and plasmogamy and karyogamy occur, resulting in a motile zygote. Each zygote can develop into a diploid thallus. The thallus bears two kinds of spore cases: zoosporangia and resting sporangia. Zoosporangia produce flagellate diploid **zoospores** that develop into new diploid thalli. Meiosis occurs within resting sporangia, producing haploid zoospores. Each zoospore has the potential to develop into a haploid thallus.

Molecular evidence suggests that chytrids were probably the earliest fungal group to evolve. Chytrids produce flagellate cells at some stage in their life history, a character that systematists trace to the protist that was the common ancestor of all opisthokonts. No other fungal group has flagellate cells. At some point in their evolutionary history, other fungal groups apparently lost the ability to produce motile cells, perhaps during the transition from aquatic to terrestrial habitats.

Zygomycetes reproduce sexually by forming zygospores

Mycologists have named more than 1100 species of **zygomycetes** (phylum Zygomycota). Of all the fungi, members of this taxon

appear most closely related to the chytrids. However, zygomycetes are not a monophyletic group, and as mycologists learn more about fungal relationships, they may divide this phylum into several taxa or reassign its members to other existing phyla.

Most zygomycetes are decomposers that live in the soil on decaying plant or animal matter (FIG. 29-8). Some zygomycetes form a type of symbiotic association (mycorrhizal relationship) with plant roots. (Recall that a symbiotic association is an intimate relationship between organisms of different species.) A few species cause disease in plants and animals, including humans.

During sexual reproduction, zygomycetes produce sexual spores, called **zygospores**. The zygospores are typically produced in spore sacs called **zygosporangia**. The hyphae in zygomycetes are coenocytic; that is, they lack regularly spaced septa. However, septa do form to separate the hyphae from reproductive structures.

Perhaps the most familiar zygomycete is the black bread mold, *Rhizopus stolonifer*, a decomposer that breaks down bread and other foods. If preservatives are not added, bread left at room temperature for a few days often becomes covered with a black, fuzzy growth. Bread becomes moldy when a spore falls on it and then germinates and grows into a mycelium (FIG. 29-9 on page 612). Hyphae penetrate the bread and absorb nutrients. Eventually, certain hyphae grow upward and develop sporangia at their tips. Clusters of more than 50,000 black asexual spores can develop within each sporangium. The spores are released when the delicate sporangium ruptures. The spores give the black bread mold its characteristic color.

Sexual reproduction in the black bread mold occurs when the hyphae of two different mating types, designated plus (+) and minus (–), grow into contact with one another. The bread mold is **heterothallic**, meaning that an individual fungal hypha mates only with a hypha of a different mating type. That is, sexual reproduction occurs only between a member of a (+) strain and one of a (–) strain, not between members of two (+) strains or members of two (–) strains. Because there are no physical differences between the two mating types, it is not appropriate to refer to them as “male” and “female.”

When hyphae of opposite mating types grow in close proximity, they signal one another with pheromones. In response to these chemical signals, the tips of the hyphae come together and form **gametangia**, which serve as gametes. Plasmogamy occurs as the gametangia fuse. Then karyogamy occurs as the (+) and (–) nuclei fuse to form the diploid zygote nucleus. The zygote develops into a zygospore. Zygospores are encased in a thick protective zygosporangium. The zygospore may lie dormant for several months. It can survive desiccation and extreme temperatures. Meiosis probably occurs at or just before germination of the zygospore.

When the zygospore germinates, an aerial hypha develops with a sporangium at the tip. Mitosis within the sporangium produces haploid spores. These spores may be all (+) spores, all (–) spores, or a mixture of (+) and (–) spores. When released, the spores germinate to form new hyphae. Only the zygote and zygospore of a black bread mold are diploid; all the hyphae and the asexual spores are haploid.

Chytrids have flagellate reproductive cells.

Figure 29-7 Life cycle of the chytrid *Allomyces arbuscula*

Allomyces alternates between multicellular haploid and multicellular diploid stages, which are similar in appearance.

CONNECT *Allomyces* produces gametes by mitosis. By what type of cell division do animals produce gametes?

Microsporidia have been a taxonomic mystery

Microsporidia are small, unicellular parasites that infect eukaryotic cells. They are opportunistic pathogens that infect animals. For example, microsporidia infect people with compromised immune systems, such as HIV-infected

individuals. Microsporidia cause a variety of diseases involving many organ systems, and some species cause lethal infections. Some species of microsporidia appear to be host-specific.

Microsporidia have two developmental stages inside their host: a feeding stage and a reproductive stage. Some microsporidian species divide into two cells by binary fission, and others divide into several cells. Some species undergo nuclear fusion

Cabisco/Visuals Unlimited

Figure 29-8 *Pilobolus*, a zygomycete that grows in animal dung

Stalked sporangia of *Pilobolus* protruding from a pile of dung, which contains an extensive mycelium of the fungus. The stalked sporangia, which are 5 to 10 mm tall, act like shotguns and forcefully discharge sporangia (the black tips) away from the dung onto nearby grass. When animals such as cattle or horses eat the grass, the spores pass unharmed through the animal's digestive tract and are deposited in a fresh pile of dung.

and meiosis before producing spores. The spores, which have thick protective walls, can pass from cell to cell inside the host or can be excreted in urine or through the skin. The spores, the only stage with distinct characters, are used to identify groups.

Each spore is equipped with a unique structure, a long, threadlike *polar tube*. When the spore enters the gut of a new host, it discharges its polar tube and penetrates the lining of the gut. Acting as a hypodermic needle, the polar tube injects the contents of the spore into the host cell (FIG. 29-10).

Microbiologists estimate that there may be more than one million species of microsporidia, but only about 1500 species have been named. Microsporidia were originally classified with yeasts and bacteria. In 1976, they were assigned to the protozoa. In the 1980s, biologists viewed microsporidia as the most primitive example of a eukaryote. They were the smallest and simplest known eukaryotes, and the genomes of some species are smaller than most bacterial genomes. Microsporidia lack mitochondria, flagella, and Golgi complexes. Their ribosomes resemble those of prokaryotes.

In 1998, British biologist Thomas Cavalier-Smith reassigned microsporidia to kingdom Fungi. Molecular studies show that microsporidia have gene sequences that indicate that they originally had mitochondria. Microbiologists now generally agree that these organisms have become simpler as they adapted to their parasitic way of life. Other molecular studies have provided additional evidence for their taxonomic relationship with fungi. Establishing that they are closely related to fungi is important in developing medications that will be effective in treating microsporidian infections. Recent genome studies suggest that microsporidia descended from a zygomycete ancestor. For now, we classify the microsporidia with the zygomycetes, but in the future they may be assigned to a separate taxon.

Glomeromycetes have a symbiotic relationship with plant roots

Glomeromycetes (phylum Glomeromycota) have coenocytic (no septa) hyphae. They reproduce asexually with large, multinucleate spores called *blastospores*. Sexual reproduction has not been documented. About 230 species of glomeromycetes have been described. Glomeromycetes were previously considered zygomycetes, but taxonomists using molecular data have determined that they form a separate monophyletic group.

Glomeromycetes are symbionts that form intracellular associations with the roots of most trees and herbaceous plants. These symbiotic associations between the hyphae of certain fungi and the roots of plants are called **mycorrhizae** (from Greek words meaning “fungus roots”) (FIG. 29-11). Glomeromycetes extend their hyphae through the cell walls of root cells but often may not penetrate the plasma membrane. As each hypha pushes forward, the plasma membrane of the root cell surrounds it. Thus, the hyphae can be thought of as fingers pushing into a glove formed by the plasma membrane. Because they penetrate the cell wall, these fungi are referred to as **endomycorrhizal fungi**.

The most widespread endomycorrhizae are called *arbuscular mycorrhizae* because the hyphae inside the root cells form branched, tree-shaped structures known as **arbuscules** (see Fig. 29-11 and Fig. 36-11b). The arbuscules are the sites of nutrient exchange between the plant and the fungus. Arbuscular mycorrhizae live entirely underground.

In mycorrhizal relationships the roots supply the fungus with sugars, amino acids, and other organic substances. The mycorrhizal fungus decomposes organic material in the soil and also benefits the plant by extending the reach of its roots. The slender mycelia are far thinner than roots and can extend into narrow spaces, absorbing nutrients that the plant could not capture on its own. Thus, with the help of the mycorrhizal fungus, the plant can also take in more nutrient minerals such as phosphorus and nitrogen.

What we have just described is a mutualistic symbiotic association: both partners benefit. Studies show that if a plant grows in phosphate-deficient soil or has a limited root system, its growth is enhanced by having a fungal partner. However, a plant in a phosphate-rich soil with a well-developed root system may not need fungal partners. For these plants, the fungus may be a parasite.

Much remains to be learned about mycorrhizal associations. Other, yet unknown, benefits of the symbiosis may further define the association as mutualistic. For example, some fungi release alkaloids that protect the plants from herbivores and pathogens. Plants also exchange nutrients with one another through fungi that connect them.

Scientists have discovered mycorrhizal fungi within ancient plant fossils in rocks that are about 400 million years old. These findings suggest that when plants moved onto the land, their fungal partners moved with them. In fact, the fungal partners may have been critical for early vascular plants to colonize the land because the fungal hyphae may have provided plants with water and minerals before their own root systems evolved.

Key Point

Like most fungi, most zygomycetes reproduce both asexually and sexually.

Figure 29-9 Life cycle of a zygomycete, the black bread mold (*Rhizopus stolonifer*)

CONNECT Identify the structures that function as the equivalent of gametes in the zygomycete life cycle. Are they haploid, diploid, or dikaryotic?

Ascomycetes reproduce sexually by forming ascospores

Ascomycetes (phylum Ascomycota) comprise a large group of fungi consisting of more than 32,000 described species. The

diverse ascomycetes include most yeasts; the powdery mildews; most of the blue-green, pink, and brown molds that cause food to spoil; decomposer cup fungi; and the edible morels and truffles.

The ascomycetes, more than any other group of fungi, affect humans. As we will discuss in a later section,

Figure 29-10 Infection by a microsporidium

ascomycetes are used to flavor cheeses, to bake bread (yeast), and to ferment alcohol. Some are enjoyed as foods (morels and truffles). Ascomycetes are used to produce antibiotics. They have also served as valuable model organisms for biologists studying cellular processes, including protein synthesis. Many fungi in this group form mycorrhizae with tree roots, and about 40% join with green algae or cyanobacteria to form lichens. On the negative side, ascomycetes cause most fungal diseases of plants and animals, including humans. For example, ascomycetes cause serious plant diseases such as Dutch elm disease, ergot disease on rye, powdery mildew on fruits and ornamental plants, and chestnut blight.

Ascomycetes are sometimes referred to as *sac fungi* because their sexual spores are produced in microscopic sacs called **asci** (sing., *ascus*). Their hyphae usually have septa, but these cross walls have pores so that cytoplasm is continuous from one cell compartment to another.

In most ascomycetes asexual reproduction involves production of spores called **conidia**, which form at the tips of certain specialized hyphae known as *conidiophores* (FIG. 29-12). Production of these spores is a means of rapidly propagating new mycelia when environmental conditions are favorable. Conidia occur in various shapes, sizes, and colors in different species. The color of the conidia produces the characteristic blue-green, pink, brown, or other tints of many of these molds.

Some species of ascomycetes are heterothallic. (Recall that heterothallic means that an individual fungal hypha mates only with a hypha of a different mating type.) Others are **homothallic**, which means that they are self-fertile and have the ability to mate with themselves. In both heterothallic and homothallic ascomycetes, sexual reproduction takes place after two gametangia come together and their cytoplasm mingles.

Let us examine the life cycle of a typical ascomycete (FIG. 29-13). In our example plasmogamy takes place as hyphae

Figure 29-11 Arbuscular mycorrhizae

This mycelium has grown into a plant root. Its hyphae branch between the cells of the root. Hyphae have penetrated through the cell walls of two root cells and have branched extensively to form arbuscules. The tip of one hypha between root cells has enlarged and serves as a vesicle that stores food. The tip of a hypha in the soil has enlarged, forming a spore. The spaces between the root cells have been magnified for clarity.

Figure 29-12 Conidia

SEM of *Penicillium* conidiophores, which resemble paintbrushes. Note the conidia pinching off from the tips of the “brushes.” Conidia are asexual reproductive cells produced by ascomycetes and some basidiomycetes. Biologists use the arrangement of conidia on conidiophores to identify species of these fungi.

Ascomycetes produce asexual spores called conidia and sexual spores called ascospores.

Figure 29-13 Life cycle of a typical heterothallic ascomycete

Sexual reproduction requires haploid mycelia of different mating types. Note the dikaryotic stage and the separation of plasmogamy and karyogamy. Steps 5 through 8 take place within an ascus in the ascocarp.

CONNECT Is each of the following haploid, diploid, or dikaryotic: conidium, ascocarp, ascospore, zygote?

of two different mating types come together and fuse. Within this fused structure, pairs of haploid nuclei, one from each parent hypha, associate but do not fuse. New hyphae, with dikaryotic cells, develop from the fused structure. The hyphae branch repeatedly until the hyphal tips reach the site where asci will be produced. As the many sac-shaped asci develop, each containing two dissimilar nuclei (one from each parent), they are surrounded by intertwining haploid (monokaryotic) hyphae. These hyphae help make a fruiting body known as an **ascocarp** (FIG. 29-14a).

Karyogamy occurs in each ascus. The two nuclei fuse and form a diploid zygote nucleus. The zygote nucleus then undergoes meiosis to form four haploid nuclei with different genotypes. One mitotic division of each of the four nuclei usually follows, resulting in eight haploid nuclei. Each haploid nucleus becomes incorporated into a thick-walled **ascospore**; thus, there are typically eight haploid ascospores within the ascus (FIG. 29-14b). The ascospores are usually released through a pore, slit, or hinged lid at the tip of the ascus. Air currents carry individual ascospores, often for long distances. If one lands in a suitable location, it germinates and forms a new mycelium. The fungus can reproduce asexually by producing conidia that can develop into new mycelia.

Phylum Ascomycota includes more than 300 species of unicellular yeasts. Asexual reproduction of yeasts is mainly by **budding**; in this process, a small protuberance (bud) grows and eventually separates from the parent cell (see Fig. 29-3). Each bud can grow into a new yeast cell.

Yeasts reproduce sexually by forming ascospores. During sexual reproduction, two haploid yeasts fuse, forming a diploid zygote. The zygote undergoes meiosis, and the resulting haploid nuclei are incorporated into ascospores. These spores remain enclosed for a time within the original cell wall, which corresponds to an ascus.

Basidiomycetes reproduce sexually by forming basidiospores

The more than 30,000 species of **basidiomycetes** (phylum Basidiomycota) include the largest and most familiar of the fungi: the mushrooms, bracket fungi, and puffballs (FIG. 29-15). Many basidiomycetes are decomposers that obtain nutrients by breaking down organic matter. Some species cause great economic loss because they cause dry rot in buildings. Certain basidiomycetes form mycorrhizae. Others, such as wheat rust and corn smut, infect important crops. A few basidiomycetes cause human disease.

Sometimes called *club fungi*, basidiomycetes derive their name from their microscopic club-shaped **basidia** (sing., *basidium*). Basidia are comparable in function to the asci of ascomycetes. Each basidium is an enlarged hyphal cell that undergoes meiosis to form four **basidiospores** (FIG. 29-16). Note that basidiospores develop on the *outside* of a basidium, whereas ascospores develop *within* an ascus.

Each individual fungus produces millions of basidiospores, and each basidiospore has the potential to give rise to a new **primary mycelium**. Hyphae of a primary mycelium consist of monokaryotic cells. The mycelium of a basidiomycete, such as the commonly cultivated mushroom *Agaricus brunnescens*, consists of a mass of white, branching, threadlike hyphae that live mostly underground. Septa divide the hyphae into cells, but as in ascomycetes, the septa are perforated and allow cytoplasmic streaming between cells.

Let us examine the life cycle of a typical basidiomycete. Asexual reproduction is less common in basidiomycetes than in other groups, so we will focus here on sexual reproduction. We begin with two compatible primary mycelia (FIG. 29-17). When in the course of its growth a hypha of a primary mycelium encounters a compatible monokaryotic hypha, typically of a different mating type, the two hyphae fuse (plasmogamy).

(a) The ascocarp (fruiting body) of the common brown cup (*Peziza badio-confusa*). This ascocarp is shaped like a saucer or bowl and is 3 to 10 cm (1 to 4 in.) wide. It is found on damp soil in woods throughout North America. Photographed in Muskegon, Michigan.

(b) Asci. Each ascus contains eight ascospores. Asci line the inner portion of the ascocarp.

(b) The elegant stinkhorn (*Phallus ravenelii*) has a foul smell that attracts flies. The flies help disperse the slimy mass of basidiospores. Fruiting bodies of elegant stinkhorns grow to 18 cm (7 in.) tall. Photographed in Pennsylvania.

Jeff Lepore/Science Source

(c) Turkey-tail (*Trametes versicolor*) is a common bracket fungus. Bracket fungi grow on both dead and living trees and produce shelf-like fruiting bodies. Basidiospores are produced in pores located underneath each shelf.

Figure 29-15 Basidiomycete fruiting bodies

As in the ascomycetes, the two haploid nuclei remain separate within each cell. In this way a **secondary mycelium** with dikaryotic hyphae, in which each cell contains two haploid nuclei, is produced. The $n + n$ hyphae of the secondary mycelium grow rapidly and extensively.

When environmental conditions are favorable, the hyphae form compact masses, called *buttons*, along the mycelium. Each button grows into a fruiting body that we know as

a mushroom. A mushroom is more formally referred to as a **basidiocarp**. Each basidiocarp consists of intertwined, matted hyphae and has a stalk and a cap. The lower surface of the cap usually consists of many thin, perpendicular plates called **gills** that radiate from the stalk to the edge of the cap.

Karyogamy takes place within the young basidia on the gills of the mushroom. The haploid nuclei fuse in the dikaryotic cells, forming diploid zygote nuclei. They are the only diploid cells that form during a basidiomycete's life cycle. Meiosis then takes place, forming four haploid nuclei with different genotypes. These nuclei move to the outer edge of the basidium. Finger-like extensions of the basidium develop, into which the nuclei and some cytoplasm move; each of these extensions becomes a basidiospore. A septum forms that separates the basidiospore from the rest of the basidium by a delicate stalk that breaks when the basidiospore is forcibly discharged. Each basidiospore can germinate and give rise to a primary mycelium.

Many basidiomycetes produce "fairy rings" in lawns and forests (**FIG. 29-18**). A fairy ring may first appear as a dark green ring surrounding an inner brown circle. The size of the ring ranges from a few centimeters to more than 15 m (about 51 ft) in diameter. The green ring consists of grass, well nourished by the nutrients released as the fungi decompose organic material. Grass dies, producing the inner brown circle, because the mass of mycelia decreases the movement of water into the area. As the fungi grow outward, the circle widens. The rings grow a few centimeters to more than a meter per year. After rainfall or irrigation, a ring of mushrooms may appear just outside the green circle. The name "fairy ring" comes from a legend that a ring of mushrooms appeared where fairies had danced in a circle the night before.

Basidiomycetes produce sexual basidiospores on the gills of basidiocarps (fruiting bodies).

Figure 29-17 Life cycle of a typical basidiomycete

Note the dikaryotic stage and the separation of plasmogamy and karyogamy. Steps 5 and 6 take place within the basidia of the basidiocarp. Asexual reproduction is uncommon in this group.

CONNECT Is each of the following haploid, diploid, or dikaryotic: basidiocarp, basidiospore, primary mycelium, zygote, secondary mycelium?

Wally Eberhart/Getty Images

Figure 29-18 A fairy ring

CHECKPOINT 29.3

- What evidence supports the hypothesis that chytrids were the earliest fungal group to evolve from the common ancestor of fungi?
- What are the distinguishing characteristics of each of the following fungal groups: zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes?
- **VISUALIZE** Use simple diagrams to illustrate how the life cycle of a typical basidiomycete differs from that of a typical ascomycete.
- Distinguish among (1) ascocarp, ascus, and ascospore and among (2) basidiocarp, basidium, and basidiospore.

29.4 Ecological Importance of Fungi

LEARNING OBJECTIVES

- 7 Summarize the ecological significance of fungi as decomposers.
- 8 Describe the important ecological role of mycorrhizae.
- 9 Characterize the unique nature of a lichen.

Fungi make vital contributions to the ecological balance of our planet. Like bacteria, most fungi are free-living decomposers, chemoheterotrophs that absorb nutrients from organic wastes and dead organisms. For example, many fungal decomposers degrade cellulose and lignin, the main components of plant cell walls. When fungi degrade wastes and dead organisms, they release water, carbon (as CO_2), and mineral components of organic compounds, and these elements are recycled (see biogeochemical cycles in Chapter 55). Without this continuous decomposition, essential nutrients would remain locked up in huge mounds of animal carcasses, feces, branches, logs,

and leaves. These nutrients would be unavailable for use by new generations of organisms, and life would eventually cease.

Fungi form important symbiotic relationships with animals, plants, bacteria, and protists. A three-way symbiotic relationship involving a fungus, a grass, and a virus has recently been reported. In the geothermal hot spots of Yellowstone National Park, a fungus infects the roots of the host grass. When infected with a specific virus, the fungus is heat tolerant and confers heat tolerance to the grass. When not infected by the virus, the fungus does not confer heat tolerance. The symbiotic relationships of fungi with other organisms have major effects on ecosystems.

Fungi form symbiotic relationships with some animals

Because animals do not have the enzymes necessary to digest cellulose and lignin, cattle and other grazing animals cannot, by themselves, obtain needed nutrients from the plant material they eat. Their survival depends on fungi that inhabit their guts because fungi, like many other microorganisms, do have the enzymes that break down these organic compounds. The fungi benefit by living in a nutrient-rich environment.

Fungi also form symbiotic associations with ants and termites. More than 200 species of ants farm fungi. Leaf-cutting ants bring leaves to their fungi and protect them from competitors and predators. The ants also disperse the fungi to new locations. In exchange, the fungi digest the leaves, providing nutrients for the ants. This symbiosis can involve other organisms. The farmed fungi can be infested by fungal parasites. In response, the ants culture bacteria (actinomycetes) that produce antibiotics to control these parasites. These symbiotic relationships, the most complex known, are the product of 50 million years of coevolution.

Mycorrhizae are symbiotic associations between fungi and plant roots

Mycorrhizae occur in about 80% of plants (and more than 90% of all plant families). As discussed in the section on glomeromycetes, mycorrhizal fungi decompose organic material in the soil and increase the surface area of a plant's roots so that the plant can absorb more water and mineral nutrients. In exchange, the roots supply the fungus with organic nutrients.

To establish and maintain a symbiotic relationship, cells of the fungi and cells of the plant roots must communicate. For example, signaling molecules from the plant root cells stimulate fungal cells to shift to a presymbiotic growth phase in which their energy metabolism increases and their hyphae branch. The fungal cells then signal the root cells, activating a signaling pathway that activates gene expression in the root cells.

The importance of mycorrhizae first became evident when horticulturalists observed that orchids do not grow unless an appropriate fungus lives with them. Similarly, many forest trees, such as pines, decline and eventually die from

Key Experiment

Is plant growth affected by fungi in the soil?

HYPOTHESIS: In low-phosphorus soils, plants that form mycorrhizal associations with fungi exhibit enhanced growth.

EXPERIMENT: Western red cedar seedlings (*Thuja plicata*) were selected for this study. Control seedlings were grown in low-phosphorus soil in the absence of the fungus. Experimental seedlings of the same age as the control plants were grown under the same conditions as the controls except that their roots formed mycorrhizal associations.

RESULTS AND CONCLUSION: Growth of the plants that formed mycorrhizal associations was significantly enhanced. Mycorrhizal associations enhance the growth of western red cedar plants. Many similar studies using other types of plants and other types of soil have confirmed the importance of mycorrhizal association to plant growth.

SOURCE: Kough, J.L., R. Molina, and R.G. Linderman, "Mycorrhizal Responsiveness of *Thuja*, *Calocedrus*, *Sequoia*, and *Sequoiadendron* Species of Western North America," *Canadian Journal of Forest Research*, Vol. 15 (1985): 1049–1054.

(b) **Mycorrhizal associations.** Experimental seedlings were grown under the same conditions as the controls, except that the fungus was present. The seedlings formed mycorrhizal associations with the fungus.

Figure 29-19 The effect of mycorrhizae on western red cedar (*Thuja plicata*) seedlings

CONNECT Biologists have discovered that many mycorrhizal fungi are sensitive to a low pH. What human-caused environmental problem may prove catastrophic for these fungi? How may this problem affect their plant partners? What measures could we take to decrease the problem?

mineral deficiencies when transplanted to mineral-rich grassland soils that lack the appropriate mycorrhizal fungi. When forest soil containing the appropriate fungi or their spores is added to the soil around these trees, they quickly resume normal growth. Studies performed with various types of plants, including cedar, have confirmed the role of mycorrhizae in plant growth (FIG. 29-19).

As we have discussed, glomeromycetes form *endomycorrhizal* connections; they infiltrate the cells of plant roots. At least 5000 species of ascomycetes and basidiomycetes also form mycorrhizal connections, but their hyphae coat the plant root rather than penetrate its cells. These species are referred to as *ectomycorrhizal fungi*. Interestingly, researchers have shown that some mycorrhizal fungi harbor bacteria in their cytoplasm. Although the role of the bacteria is not yet clear, their presence suggests that they may be members of a three-way partnership: fungus, plant, and bacteria.

Mycorrhizal fungi connect plants, allowing nutrient transfer among them. Scientists have measured the movement of organic

materials from one tree species to another through shared mycorrhizal connections. Mycorrhizal fungi also release chemicals that protect the plant against herbivores and pathogens.

Mycorrhizae improve the soil by decreasing water loss and erosion. Ecologists are studying the role of mycorrhizal fungi in reclaiming soils damaged by pollution. For example, mycorrhizae can modify toxic heavy metals, such as cadmium, so that plants cannot absorb them.

A lichen consists of one or more fungi and a photoautotroph

Although a **lichen** looks like a single organism, it is actually a compound organism, a combination of one or more fungi and a *photoautotroph* (FIG. 29-20a). Almost one-fifth of all known fungal species form these symbiotic relationships. About 14,000 kinds of lichens have been described. Fossils suggest that fungi developed symbiotic partnerships with photoautotrophs before the evolution of vascular plants.

(a) This cross section of a typical lichen shows distinct layers. The soredium (pl., *soredia*), an asexual reproductive structure, consists of clusters of algal or cyanobacterial cells enclosed by fungal hyphae.

(b) Lichens vary in color, shape, and overall appearance. Three growth forms—crustose, foliose, and fruticose—are shown on a tree trunk in Massachusetts.

Figure 29-20 Lichens

These organisms are a combination of a fungus and an alga or cyanobacterium.

The photoautotrophic component of a lichen is a green alga, a cyanobacterium, or both. The fungus is typically an ascomycete, although a basidiomycete is the fungal partner in some tropical lichens. In 2016 it was reported that many lichens may include both an ascomycete and a unicellular basidiomycete (a yeast) as the fungal partners. Most photoautotrophic organisms found in lichens also occur as free-living species in nature, but the fungal components are generally found only as a part of the lichen. Typically, the fungus forms most of the lichen thallus (body). The fungus surrounds hundreds of photosynthetic partners and holds them in place. Lichens are named for the fungal component.

In the laboratory, researchers can isolate the fungal and photoautotrophic components of some lichens and grow them separately in appropriate culture media. The photoautotroph grows more rapidly when separated, whereas the fungus grows more slowly and requires many complex carbohydrates. Neither organism resembles a lichen in appearance when grown separately. The photoautotroph and fungus can be sometimes reassembled as a lichen thallus, but only if they are placed in a culture medium under conditions that cannot support either of them independently.

What is the nature of this partnership? The lichen was originally considered a definitive example of mutualism. The photoautotroph carries on photosynthesis, producing energy-rich carbon compounds for both members of the lichen. It is unclear how the photoautotroph benefits from the relationship. Some biologists have suggested that the photoautotroph obtains water

and nutrient minerals from the fungus as well as protection against desiccation. More recently, researchers have suggested that the lichen partnership is not really a case of mutualism but one of controlled parasitism of the photoautotroph by the fungus.

Lichens typically exhibit one of three different growth forms (**FIG. 29-20b**). *Crustose lichens* are flat and grow tightly against their substrate (the surface they are growing on). *Foliose lichens* are also flat, but they have leaflike lobes and are not as tightly pressed to the substrate. *Fruticose lichens* grow erect and have many branches.

Able to tolerate extremes of temperature and moisture, lichens grow in almost all terrestrial environments except polluted cities. They exist farther north than any plants of the arctic region and are equally at home in the steaming equatorial rain forest. They grow on tree bark, leaves, and exposed rock surfaces, from solidified lava to tombstones. In fact, lichens are often the first organisms to inhabit rocky areas, and their growth in these areas is important in forming soil from rock. They secrete acid that gradually etches tiny cracks in the rock, releasing minerals. This process sets the stage for further disintegration of the rock by wind and rain. When the lichens themselves die and are decomposed, they become part of the soil.

Reindeer mosses of the arctic region, which serve as the main source of food for migrating herds of caribou, are actually lichens, not mosses. Some lichens produce colored pigments. One of them, orchil, is used to dye wool; another, litmus, is widely used in chemistry laboratories as an acid–base (pH) indicator.

Lichens vary greatly in size. Some are almost invisible, whereas others, such as the reindeer mosses, may cover many square kilometers of land with an ankle-deep growth. Growth proceeds slowly; the radius of a lichen may increase by less than 1 mm each year. Some mature lichens are thought to be thousands of years old.

Lichens absorb minerals from the air, rainwater, and the surface on which they grow. They cannot excrete the elements they absorb, and perhaps for this reason they are extremely sensitive to toxic compounds. This sensitivity was first reported in 1866 by a Finnish biologist who observed that lichens growing on tree trunks in Paris were poorly developed or sterile. He deduced that lichens could be used to measure air purity. Today, reduction in lichen growth is used as a sensitive indicator of air pollution, particularly from sulfur dioxide. In one study, investigators demonstrated a relationship between lung cancer and air pollution by comparing the locations of low lichen biodiversity (and therefore of air pollution) with the locations of lung cancer deaths in young males. The return of lichens to an area indicates an improvement in air quality.

Lichens reproduce mainly by asexual means, usually by fragmentation, a process in which special dispersal units of the lichen, called **soredia** (sing. *soredium*), break off and, if they land on a suitable surface, establish themselves as new lichens. Soredia contain cells of both partners. In some lichens the fungus produces ascospores, which may be dispersed by wind and find an appropriate algal partner only by chance.

CHECKPOINT 29.4

- **CONNECT** What is the ecological importance of fungal decomposers?
- What are some ways in which the relationship between a plant root and a mycorrhizal fungus is mutualistic?
- Many biologists consider a lichen an example of controlled parasitism. In this view, which component is the likely parasite, and which is the likely host?

29.5 Economic, Biological, and Medical Impact of Fungi

LEARNING OBJECTIVES

- 10 Summarize some specific ways that fungi affect humans economically.
- 11 Summarize the importance of fungi to biology and medicine; describe how fungi infect plants and humans, describing at least one fungal animal disease and one fungal plant disease.

The same powerful digestive enzymes that fungi use to decompose wastes and dead organisms can also be used with great efficiency to reduce wood, fiber, and food to their basic components. Many species of basidiomycetes have enzymes

that break down the lignin in wood. (Lignin is the second most abundant organic compound on Earth, second only to cellulose.) From the human perspective, various fungi cause incalculable damage to stored goods and building materials each year. Bracket fungi, for example, cause enormous losses by decaying wood, both in living trees and in stored lumber.

Some fungi cause serious diseases in animals and plants, yet fungi also contribute to our quality of life. They are responsible for economic gains as well as losses. People eat them and grow them to make various medications, such as penicillin. We use them to make certain industrial chemicals and for bioremediation. Renewable fuel companies are actively searching for fungi and other microbes that can produce fuel. For example, a fungus has been discovered that synthesizes 55 hydrocarbons, perhaps to inhibit the growth of other organisms. Researchers may be able to use the genes of this fungus to engineer other microorganisms to produce fuel more efficiently.

Fungi provide beverages and food

Humans exploit the ability of yeasts to produce bread and alcoholic beverages. Yeasts produce ethyl alcohol and carbon dioxide from glucose and other sugars by fermentation (see Chapter 8).

Yeast species of the genus *Saccharomyces* (ascomycetes) are used to produce wine, beer, and other fermented beverages. Wine is produced when yeasts ferment fruit sugar, and beer results when yeasts ferment sugar derived from starch in grains (usually barley).

Saccharomyces cerevisiae, referred to as baker's yeast, is used to bake bread, pizza, and other wheat products. During the process of making bread, carbon dioxide produced by yeast becomes trapped in dough as bubbles, causing the dough to rise and giving leavened bread its light quality. Both the carbon dioxide and the alcohol produced by the yeast escape during baking.

The unique flavor of cheeses such as Roquefort, Brie, Gorgonzola, and Camembert is produced by species of *Penicillium*. For example, *P. roquefortii*, found in caves near the French village of Roquefort, is used to make Roquefort cheese. By French law, only cheeses produced in this area can be called Roquefort cheese. (The blue spots in Roquefort and certain other cheeses are masses of conidia.)

Aspergillus tamarii and certain other fungi are used to produce traditional soy sauce by fermenting soybeans with the fungi for at least three months. Soy sauce enriches other foods with more than just its special flavor. It also adds vital amino acids from both the soybeans and the fungi themselves, which, in some parts of the world, supplement a low-protein rice diet.

Among the basidiomycetes, there are some 200 kinds of edible mushrooms and about 70 species of poisonous ones. Many edible mushrooms are cultivated commercially. The mushroom *Agaricus brunnescens* is the principal fungal species grown extensively for food. About 30 other mushroom species, such as oyster, shiitake, portobello, and straw mushrooms, are available in supermarkets. Morels, which superficially resemble mushrooms, and truffles, which produce underground fruiting bodies, are ascomycetes (FIG. 29-21). Truffles are now cultivated as mycorrhizal fungi on the roots of tree seedlings.

(a) The yellow morel (*Morchella esculenta*). This morel grows 6 to 10 cm (2.5 to 4 in.) tall. It is found throughout North America. Photographed in Michigan.

(b) The Oregon white truffle (*Tuber gibbosum*). This truffle, which is found underground near Douglas firs and possibly oak trees in British Columbia and northern California, is 1 to 5 cm (0.4 to 2 in.) wide. People find these subterranean ascocarps with the help of trained dogs or pigs. Here, truffles are shown whole and sectioned to show the conspicuous white, marbled tissue.

Figure 29-21 Edible ascomycetes

Edible and poisonous mushrooms can look very much alike and may even belong to the same genus. There is no simple way to tell them apart; an expert must identify them. Some of the most poisonous mushrooms belong to the genus *Amanita* (FIG. 29-22). Toxic species of this genus have been appropriately called such names as “destroying angel” (*A. virosa*) and “death cap” (*A. phalloides*). Eating a single mushroom of either species can be fatal.

Certain species of mushrooms cause intoxication and hallucinations. The sacred mushrooms of the Aztecs—*Conocybe* and *Psilocybe*—are still used in religious ceremonies by native peoples of Central America for their hallucinogenic properties. The chemical ingredient *psilocybin* is responsible for the trances and visions experienced by those who eat these mushrooms. Ingestion of psychoactive mushrooms is dangerous because negative reactions vary considerably, from mild indigestion, sweating, and heart palpitations, to death. In addition, the possession and use of such mushrooms are illegal in the United States and some other countries.

Fungi are important to modern biology and medicine

As discussed in Chapter 17, yeast *Saccharomyces cerevisiae* has served as a model eukaryotic cell (see Fig. 29-3). It was the first eukaryote whose genome was sequenced, and with its 6275 genes, it has the smallest genome of any eukaryotic model organism. Molecular biologists are in the process of determining the functions of the proteins encoded by its genes. Biologists have used *S. cerevisiae* to study molecular genetics, including how genes regulate cell division. Researchers continue to use this yeast to study such problems as genetic recombination and the correlation between cell age and cancer. *Saccharomyces cerevisiae* is also being used to study the mechanism of action of antifungal drugs and resistance to these drugs.

Biologists have used the ascomycete *Aspergillus nidulans*, an opportunistic pathogen of humans, to study mitosis and other cell processes. This fungus has provided valuable knowledge about the genetics of microtubules. Biologists are using recombinant DNA techniques to manipulate yeasts and certain filamentous fungi to produce important biological molecules, such as hormones. Among the many genes that have been cloned in yeast are those for insulin, human growth hormone, and molecules important in immune function. These procedures allow researchers to produce unlimited amounts of these compounds for study and eventual medical use.

Fungi produce useful drugs and chemicals. Discovered in 1928 by British bacteriologist Alexander Fleming, penicillin, produced by the mold *Penicillium notatum*, is still among the most widely used and effective antibiotics (see Chapter 1). Other drugs derived from fungi include the cephalosporin antibiotics (produced by *Cephalosporium*), statins (used to lower blood cholesterol levels), and cyclosporine (used to suppress immune responses in patients who receive organ transplants). Fumagillin, a chemical produced by the ascomycete *Aspergillus fumigatus*, inhibits the formation of new blood vessels. Because solid tumors need a rich blood supply, fumagillin shows promise as an anticancer agent. Fumagillin is also used to treat diseases caused by microsporidia. Researchers have identified several other promising compounds produced by fungi that are antiviral or that destroy cancer cells.

The ascomycete *Claviceps purpurea* infects the flowers of rye plants and other cereals. It produces a structure called an *ergot* where a seed would normally form in the grain head. When livestock eat this grain or when humans eat bread made from ergot-contaminated rye flour, they may be poisoned by the extremely toxic substances in the ergot. However, some ergot compounds are now used clinically in small quantities as drugs to induce labor, to stop uterine bleeding, to treat high blood pressure, and to relieve one type of migraine headache.

James W. Richardson/CBR Images

Figure 29-22 Poisonous mushrooms

The destroying angel (*Amanita virosa*) is an extremely poisonous mushroom that is distinguished, as are other amanitas, by the ring of tissue around its stalk and by the underground cup from which the stalk protrudes. About 50 g (2 oz) of this mushroom can kill an adult man. The destroying angel, which is 7.5 to 20 cm (3 to 8 in.) tall, is found in grass or near trees throughout North America.

Fungi are used in bioremediation and to biologically control pests

Some fungi can biodegrade pesticides, herbicides, coal tars, and petroleum. Fungi convert these products into carbon dioxide and the basic elements of which they are composed. These fungi can be used along with certain bacteria to decontaminate farm land and to clean up oil spills.

Researchers are investigating fungi—for example, certain species of microsporidia—for the biological control of pathogens and insect pests. Some of these species are already being used to parasitize insect pests. In some cases, they interfere with reproduction in their insect host. It should be noted that some microsporidia may pose a threat to beneficial insects. For example, a microsporidian has been implicated as one factor in the die-off of honeybee colonies.

Some fungi cause diseases in humans and other animals

Certain ascomycetes cause superficial infections in which only the skin, hair, or nails are infected. Ringworm, athlete's foot, and jock itch are examples of superficial fungal infections. Because these fungi infect dead layers of skin that are not fed by capillaries, the immune system cannot launch an effective response.

Many pathogenic fungi are opportunists that cause infections only when the body's immune system is compromised,

such as in patients infected with HIV. Cancer patients and organ transplant recipients who are given medication to suppress their immune systems are also at risk. *Candida* is an ascomycete that inhabits the human mouth and vagina. The immune system and the normal bacteria of these regions normally prevent this yeast from causing infection. However, when the immune system is compromised, *Candida* multiplies, causing thrush, a painful yeast infection of the mouth, throat, and vagina.

The ascomycete *Aspergillus fumigatus* is usually harmless but causes aspergillosis in people with lowered immune function. During the course of aspergillosis, the fungus can invade the lungs, heart, brain, kidneys, and other vital organs and cause death.

Other fungi also infect internal tissues and organs and may spread through many regions of the body. Histoplasmosis, for example, is a lung infection caused by inhaling spores of a fungus common in soil contaminated with bird feces. Most people in the eastern and midwestern parts of the United States have been exposed to this fungus at some time, and an estimated 40 million Americans have had mild infections. Fortunately, the infection is usually confined to the lungs and is of short duration, but if the infection spreads through the blood to the heart, brain, or other parts of the body, it can be serious and sometimes fatal.

Some fungi produce poisonous compounds collectively called **mycotoxins**. A few species of *Aspergillus*, for example, produce potent mycotoxins called **aflatoxins** that harm the liver and are known carcinogens. Foods on which aflatoxin-producing fungi commonly grow include peanuts, pecans, corn, and other grains. Other foods that may contain traces of aflatoxins include animal products such as milk, eggs, and meat (from animals that consumed feed contaminated by aflatoxin). Avoiding aflatoxin in the diet is impossible, but exposure should be minimized as much as possible. Any human food or animal forage product that has become moldy should be suspected of aflatoxin contamination and should be discarded.

Fungi contribute to sick-building syndrome, a situation in which occupants of a building experience acute adverse health effects linked to the time they spend in a given building. Mold-related insurance claims amount to hundreds of millions of dollars each year. When conditions are moist, molds can grow on carpets, leather, cloth, wood, insulation, and food. Mold spores, fragments, and aerosol mold products make their way into the air, and people are exposed through inhalation as well as by skin contact.

Exposure to molds and their toxins has been linked to depressed immune function, irritation of the throat and respiratory passageways, infection, and toxicity. The most common responses to mold exposure are reactions that range from mild to severe illnesses, including hay fever, sinusitis, asthma, and dermatitis.

Fungi cause many important plant diseases

Fungi are more destructive to plants than any other disease-causing organism. They are responsible for about 70% of all major crop diseases. Fungi cause serious epidemic diseases that spread rapidly and often result in complete crop failure. Fungal plant diseases costs billions of dollars in agricultural damage yearly.

All plants are apparently susceptible to some fungal infection. Damage may be localized in certain tissues or structures of the plant, or the disease may be systemic and spread throughout the entire plant. Fungal infections may cause stunting of plant parts or of the plant and may cause wartlike growths or kill the plant.

A plant often becomes infected after hyphae enter through stomata (pores) in the leaf or stem or through wounds in the plant body (FIG. 29-23). Alternatively, the fungus may produce *cutinase*, an enzyme that dissolves the waxy cuticle that covers the surface of leaves and stems. After dissolving the cuticle, the fungus easily invades the plant tissues. As the mycelium grows, it may stay mainly between the plant cells, or it may penetrate the cells. Parasitic fungi often produce special hyphal branches called **haustoria** (sing., *haustorium*) that penetrate the host cells and obtain nourishment from the cytoplasm.

Ascomycetes cause serious plant diseases, including powdery mildew, chestnut blight, Dutch elm disease, apple scab, wilt on potatoes, and brown rot, which attacks cherries, peaches, plums, and apricots (FIG. 29-24a).

Basidiomycetes cause smuts and rusts that attack corn, wheat, oats, and other grains (FIGS. 29-24b and c). Some fungal parasites, such as the basidiomycete *Puccinia graminis*, which causes black stem rust of wheat, have complex life cycles that involve two or more different host plants and the production of several kinds of spores. Before the late 1950s, black stem rust outbreaks occurred every few years somewhere in the world, destroying entire wheat crops. By the early 1960s, Norman Borlaug, winner of the Nobel Peace Prize in 1970, and other researchers had developed rust-resistant varieties of wheat, heralding in the green revolution. However, new mutations have put *Puccinia* and wheat rust back in the news. The new strain has spread through parts of Africa and into the Middle East. Each fungus releases billions of spores, which the wind

Figure 29-23 How a fungus parasitizes a plant

In this example, the hypha enters the leaf through a stoma. The hypha grows, branching extensively through the internal air spaces, and penetrates plant cells with specialized hyphal extensions called haustoria.

can blow for hundreds of miles, spreading the fungus to new regions of the world. Its spread may lead to widespread food shortages. The genomes of several *Puccinia* species have been sequenced, and researchers are developing methods to quickly diagnose the diseases they cause. They are also working to develop new varieties of disease-resistant wheat.

CHECKPOINT 29.5

- **CONNECT** In what ways (both positive and negative) are fungi important in modern biology and medicine?
- **CONNECT** Can fungi be beneficial to plants? In what ways are they harmful?

(a) Brown rot of peaches. This disease is caused by *Monilinia fruticola*, an ascomycete. Photographed in Oregon.

(b) Corn smut on an ear of sweet corn. This fungal disease is caused by *Ustilago maydis*, a basidiomycete.

(c) Black stem rust infection on wheat (*Triticum* sp.) stem. This plant disease is caused by *Puccinia graminis*, a basidiomycete.

Figure 29-24 Fungi that cause plant diseases

Summary: Focus on Learning Objectives

29.1 Characteristics of Fungi (page 604)

1 Describe the distinguishing characteristics of fungi.

- **Fungi** are eukaryotic heterotrophs that secrete digestive enzymes onto their food source and then absorb the pre-digested food. Fungi are characterized by cell walls that contain **chitin**.

2 Describe the body plan of a fungus.

- A fungus may be a unicellular **yeast** or a filamentous, multicellular **mold**. The body of most multicellular fungi consists of long, threadlike filaments called **hyphae** that branch and form a tangled mass called a **mycelium**.
- In most fungi, perforated **septa**, or cross walls, divide the hyphae into individual cells. In some fungi, the hyphae are **coenocytes** that form an elongated, multinuclear cell.

29.2 Fungal Reproduction (page 605)

3 Describe the life cycle of a typical fungus, including sexual and asexual reproduction.

- Most fungi reproduce both sexually and asexually by means of **spores**. Spores are produced on aerial hyphae. When fungal spores land in a suitable spot, they germinate.
- When fungi of two different mating types meet, their hyphae fuse, a process called **plasmogamy**. The cytoplasm fuses, but the nuclei remain separate. The fungi enter a **dikaryotic** ($n + n$) stage in which each new cell formed has one nucleus of each type.
- **Karyogamy**, fusion of the nuclei, takes place in the hyphal tip and results in a diploid ($2n$) **zygote nucleus**.
- Meiosis produces four genetically different haploid (n) nuclei. Each nucleus becomes part of a spore. When the spores germinate, they form new mycelia by mitosis.
- Genetically similar asexual spores are produced by mitosis. When these spores germinate, they also develop into mycelia.

29.3 Fungal Diversity (page 607)

4 Give arguments to support the hypothesis that fungi are opisthokonts, more closely related to animals than to plants.

- Like animals, some fungi have flagellate cells—for example, chytrid gametes and spores—and the flagellate cells propel themselves with a single posterior flagellum. Also like animal cells, fungal mitochondria have platelike cristae.
- Based on chemical and structural characters, fungi are classified, along with animals and choanoflagellates, as **opisthokonts**.

5 Give arguments to support the hypothesis that chytrids may have been the earliest fungal group to evolve from the most recent common ancestor of fungi.

- **Chytrids**, or **chytridiomycetes**, produce flagellate spores at some stage in their life cycle. No other fungi have flagella. Thus, chytrids probably were the earliest fungi to evolve; the most recent common ancestor of all fungi was a flagellate protist.

6 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.

- Chytrids reproduce both asexually and sexually. Their gametes and zoospores are flagellate. *Allomyces*, a common chytrid, spends part of its life as a multicellular haploid thallus and part as a multicellular diploid thallus. The haploid **thallus** produces two types of flagellate gametes that fuse. Both plasmogamy and karyogamy occur, producing a flagellate zygote. The diploid thallus bears zoosporangia that produce diploid **zoospores** and resting sporangia in which haploid zoospores form by meiosis. The haploid zoospores form new haploid thalli.
- **Zygomycetes**, such as the black bread mold, *Rhizopus*, form a haploid thallus that produces both asexual spores and sexual spores. Asexual spores germinate and form new thalli. In sexual reproduction hyphae of two different haploid mating types form gametangia. Plasmogamy occurs as the gametangia fuse. Karyogamy occurs, and a diploid zygote is formed; the zygote develops into a **zygospore**. Meiosis produces recombinant haploid zygospores. When zygospores germinate, each hypha develops a sporangium at its tip. Spores are released and develop into new hyphae.
- **Microsporidia**, currently classified as zygomycetes, are opportunistic pathogens that penetrate and infect animal cells with their long, threadlike *polar tubes*.
- **Glomeromycetes** have coenocytic hyphae. They reproduce asexually with large, multinucleate spores called

blastospores. Glomeromycetes are symbionts that form intracellular associations called **mycorrhizae** with the roots of plants. Because they extend their hyphae into root cells, glomeromycetes are **endomycorrhizal fungi**. The most common endomycorrhizae are called *arbuscular mycorrhizae* because the hyphae inside the root cells form branched, tree-shaped structures known as **arbuscules**.

- **Ascomycetes** include yeasts, cup fungi, morels, truffles, and blue-green, pink, and brown molds. Some ascomycetes form mycorrhizae; others form lichens. Ascomycetes produce asexual spores called **conidia**; they produce sexual spores called **ascospores** in saclike **asci**. The asci line a fruiting body called an **ascocarp**.
- In ascomycetes haploid mycelia of opposite mating types produce septate hyphae. Plasmogamy occurs, and nuclei are exchanged. A dikaryotic ($n + n$) stage occurs in which hyphae form and produce asci and an ascocarp. Karyogamy occurs, followed by meiosis. The recombinant nuclei divide by mitosis, producing eight haploid nuclei that develop into ascospores. When the ascospores germinate, they can form new mycelia.
- **Basidiomycetes** include mushrooms, puffballs, bracket fungi, rusts, and smuts.
- These fungi produce sexual spores called **basidiospores** on the outside of a **basidium**. Basidia develop on the surface of **gills** in mushrooms; mushrooms are a type of **basidiocarp** (a fruiting body).
- Hyphae in the basidiomycetes have septa. Plasmogamy occurs with the fusion of two hyphae of different mating types. A dikaryotic **secondary mycelium** forms. Then a basidiocarp develops, and basidia form. Karyogamy occurs, producing a diploid zygote nucleus. Meiosis produces four haploid nuclei that become basidiospores. When basidiospores germinate, they form haploid **primary mycelia**.

29.4 Ecological Importance of Fungi (page 618)

7 Summarize the ecological significance of fungi as decomposers.

- Most fungi are decomposers that break down organic compounds in dead organisms, leaves, garbage, and wastes into simpler nutrients that can be recycled.

8 Describe the important ecological role of mycorrhizae.

- Mycorrhizae are mutualistic associations between fungi and the roots of plants. The fungus supplies water and nutrient minerals to the plant, and the fungus obtains organic compounds from the plant. Glomeromycetes form endomycorrhizae with roots. Some ascomycetes and basidiomycetes are **ectomycorrhizal fungi** that form mycorrhizae when their hyphae coat tree roots, but do not penetrate the root cells.

9 Characterize the unique nature of a lichen.

- A **lichen** is a combination of one or more fungi and a photoautotroph (an alga or cyanobacterium). In this symbiotic relationship, the photoautotroph provides the fungus with organic compounds. The fungus may provide the photoautotroph with shelter, water, and minerals. Lichens have three main forms: crustose, foliose, and fruticose.

29.5 Economic, Biological, and Medical Impact of Fungi (page 621)

10 Summarize some specific ways that fungi affect humans economically.

- Fungi cause huge economic losses by damaging food and crops. On the other hand, some fungi, like mushrooms, are foods; others, like yeasts, are used to produce beer, wine, and bread; and still others are used to produce cheeses or industrial chemicals.

11 Summarize the importance of fungi to biology and medicine; describe how fungi infect plants and humans, describing at least one fungal animal disease and one fungal plant disease.

- Biologists use the yeast *Saccharomyces cerevisiae* and other fungi as model organisms for research in molecular biology and genetics. Fungi are also being investigated for the biological control of insects.
- Fungi are used to make many medications, including penicillin and other antibiotics; they are used in bioremediation and to control pests biologically.
- Fungi are opportunistic pathogens in humans. They cause human diseases, such as histoplasmosis; some fungi produce **mycotoxins**, such as *aflatoxins*, which can cause liver damage and cancer.
- Fungal hyphae infect plants through stomata. Hyphal branches called **haustoria** penetrate plant cells and obtain nourishment from the cytoplasm. Fungi cause many important plant diseases, including brown rot, corn smut, and wheat rust.

Test Your Understanding

Know and Comprehend

1. Fungi are (a) eukaryotes and opisthokonts (b) prokaryotes and opisthokonts (c) flagellate and dikaryotic (d) autotrophic eukaryotes (e) heterotrophs with cellulose cell walls
2. Which of the following fungi does *not* have a mycelium? (a) black bread mold (b) yeast (c) decomposer cup fungus (d) cultivated mushroom (e) *Penicillium*
3. A cell described as $n + n$ is (a) monokaryotic (b) diploid (c) haploid (d) coenocytic (e) dikaryotic
4. With the exception of chytridiomycetes, fungi are generally disseminated by (a) water currents (b) fragmentation of hyphae (c) soredia (d) airborne spores (e) flagellate zoospores
5. Which statement is *not* true of the chytrids? (a) they are simple aquatic fungi (b) they produce motile cells with single, posterior flagella (c) they undergo both sexual and asexual reproduction (d) their cells are dikaryotic (e) they were the earliest fungi to evolve

6. Which statement is *not* true of the zygomycetes? (a) many members of this group form endomycorrhizae with tree roots (b) their sexual spores are called zygospores (c) they undergo both sexual and asexual reproduction (d) plasmogamy and karyogamy occur (e) they have coenocytic hyphae
7. Glomeromycetes (a) reproduce mainly by sexual spores called glomerospores (b) are characterized by unique structures called polar tubes (c) associate with cyanobacteria to form lichens (d) include many opportunistic pathogens that cause human disease (e) form arbuscular endomycorrhizae with tree roots
8. The ascomycete life cycle typically includes (a) mainly diploid thalli (b) the formation of a thick zygosporangium (c) the production of eight haploid ascospores within an ascus (d) the production of microsporidia (e) the production of ascospores, zoospores, and conidia at different stages
9. Which statement is *not* true of the basidiomycetes? (a) they produce a secondary mycelium with $n + n$ hyphae (b) their sexual spores are called basidiospores (c) they have a diploid thallus that produces zoospores (d) reproduction is mainly sexual (e) they have microscopic basidia
10. A compound organism consisting of a photoautotroph and a fungus is called (a) an arbuscular endomycorrhiza (b) an ectomycorrhiza (c) a lichen (d) a pathogenic agent (e) an aflatoxin
11. Mutualistic associations between fungi and the roots of plants are called (a) lichens (b) mycorrhizae (c) pathogenic associations (d) parasitic haustoria (e) mycotoxic symbioses
12. When a fungus infects a plant, it (a) infiltrates leaves with lichens (b) forms relationships by attaching mycorrhizae to stems (c) secretes powerful digestive juices onto the leaves (d) uses haustoria to dissolve roots (e) enters leaves or stems through stomata

Apply and Analyze

13. **VISUALIZE** The secondary mycelium of a basidiomycete is shown here. (a) How would you describe its cells? (b) What stage of its life cycle is it in? (c) Draw the next steps in this stage of its life cycle.

14. Explain the statement "Mushrooms are like the tips of icebergs." If you do not see mushrooms in your lawn, can you conclude that no fungi live there? Why or why not?

Evaluate and Synthesize

15. **EVOLUTION LINK** Justify (a) classifying fungi as opisthokonts, (b) classifying microsporidia as fungi, and (c) grouping ascomycetes and basidiomycetes as sister clades.
16. **CONNECT** The development of safe and effective antifungal agents presents a daunting challenge to researchers. Explain. (*Hint: Drugs that combat bacterial diseases typically target differences between bacterial cells and those of the host.*)
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Develop an argument for or against the use of scientific resources, including the latest technology, to sequence the genomes of fungi.

30 An Introduction to Animal Diversity

KEY CONCEPTS

- 30.1** Animals are multicellular, eukaryotic heterotrophs composed of cells specialized to perform specific functions. Most animals are diploid organisms that reproduce sexually, and most have a nervous system and a muscular system.
- 30.2** Animals evolved in marine environments, and most animal phyla still have members that inhabit marine environments. However, many animals are adapted to life in fresh water and others to terrestrial habitats.
- 30.3** The common ancestors of animals are choanoflagellates; choanoflagellates, fungi, and animals are a monophyletic group known as opisthokonts.
- 30.4** Biologists classify animals based on many characteristics, including their morphology (structure), features of their early development, and molecular data; biologists agree that bilateral animals split into at least three major clades.

PHOTO: Coral reef ecosystems, the most diverse of all marine environments. Below the swimming green sea turtle (*Chelonia mydas*), identify purple tube sponges (*Aplysina archeri*) and coral. Also find a pair of queen angelfish (*Holocanthus ciliaris*), as well as orange elephant ear sponges (*Agelas clathrodes*) and an azure vase sponge (*Callyspongia plicifera*). Which of these animals might be mistaken for a plant or rock? (Photographed in Bonaire, Caribbean Netherlands, Atlantic Ocean.) Georgette Douwma/Getty Images

Although members of most animal species are readily recognizable as animals, the identity of some others is less obvious. Early naturalists thought sponges were plants because they were anchored in one place. Many people still mistake certain marine animals, such as sponges and corals, for plants (see photograph). Locomotion is not a requirement for being classified as an animal.

Animal phylogeny is an exciting and rapidly changing field of study. Biologists have described and named more than 1.5 million species of animals, and 15,000 to 20,000 new species are named each year. Millions more probably remain to be discovered and classified. Interestingly, an estimated 99% of all animal species that ever inhabited our planet are extinct. Taxonomists have assigned the extant (living) animals to about 35 major groups (phyla). Molecular studies have confirmed that many of these groups are **monophyletic**; that is, they consist of *all* the descendants and *only* the descendants of a common ancestor. (Recall from Chapter 23 that a monophyletic group is called a **clade**.)

Animal groups that are not monophyletic have been split or reorganized, with some members of the groups being reassigned to other taxa. It is important to remember that the classification of animals and the relative positions of animal groups are a work in progress. As they consider new data, systematists redraw the tree of animal life.

In this chapter we discuss the characteristics of animals and their habitats. We then explore animal origins and some of the criteria biologists use to determine evolutionary relationships and to classify animals. Finally, we introduce the major animal groups, including the three major clades of bilateral animals.

30.1 Animal Characteristics

LEARNING OBJECTIVE

- 1 Describe several characteristics common to most animals.

Animals are so diverse that for almost any definition we can find exceptions. We can best describe animals by the characteristics they share:

1. Animals are multicellular eukaryotes. In contrast to plants, algae, and fungi, animal cells lack cell walls. Instead, structural support depends on an **extracellular matrix**, which the cells secrete (see Chapter 4). Collagen, the main structural protein in the extracellular matrix, forms very tough fibers. Collagen is an important *shared derived character* in animals (see Chapter 23).
2. Animals are **heterotrophs**. As consumers, they depend on producers for their raw materials and energy. In contrast to the fungi, most animals ingest their food first and then digest it inside the body, usually within a digestive system.
3. Cells that make up the animal body are specialized to perform specific functions. In all but the simplest animals, cells are organized to form tissues, and tissues are organized to form organs. In small animals with simple body plans, life processes such as gas exchange, circulation of materials, and waste disposal can take place by diffusion of gases and other substances directly to and from the environment. In larger animals, specialized organ systems perform these functions.
4. Animals have diverse body plans. The term *body plan* refers to the basic structure and functional design of the

body. An animal's body plan and lifestyle are adapted to its methods of obtaining food and reproducing.

5. Most animals are capable of locomotion at some time during their life cycle. Some animals (such as sponges and corals) move about as larvae (immature forms) but are **sessile** (firmly attached to the ground or some other surface) as adults (see chapter-opening photograph).
6. Most animals have nervous systems and muscle systems that enable them to respond rapidly to stimuli in their environment.
7. Most animals are diploid organisms that reproduce sexually, with large, nonmotile eggs and small, flagellate sperm. A haploid sperm unites with a haploid egg, forming a diploid **zygote** (fertilized egg).
8. Animals go through a period of embryonic development. The zygote undergoes **cleavage**, a series of mitotic cell divisions. During cleavage the zygote develops into a hollow ball of cells called a **blastula**. Although some animals develop directly into adults, the majority first develop into a **larva**, a sexually immature form that may look very different from the adult (**FIG. 30-1**). The larva differs from the adult in many ways, including where it lives (its habitat), how it moves, and what it eats. Larvae typically go through **metamorphosis**, a developmental process that converts the immature animal into a juvenile form that can then grow into an adult.

CHECKPOINT 30.1

- **CONNECT** For centuries, scientists classified sponges as plants, but now they are classified as animals. What characteristics do sponges share with other animals?

(a) **Spiny lobster larva.** Over a period of months, the larva passes through several stages before becoming an adult.

(b) **Adult spiny lobster.** The adult has two long antennae used to sense movement. Spiny lobsters lack large claws. The spines on their back help protect them. In this image you can see the two large spines above the animal's eyes. Spiny lobsters leave their hiding places at night to hunt.

Figure 30-1 Larva and adult spiny lobster

Most animals go through a larva stage before developing into an adult. The larva usually differs from the adult in size, appearance, and lifestyle.

30.2 Adaptations to Ocean, Freshwater, and Terrestrial Habitats

LEARNING OBJECTIVE

- 2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

Fossil evidence suggests that animals first evolved in shallow, marine environments during the Proterozoic eon, at least 600 million years ago (mya; see Chapter 21). Although animals are now distributed in virtually every environment, at least some members of most animal phyla still inhabit marine environments.

Marine habitats offer many advantages

The buoyancy of sea water provides support, and its large volume keeps the water temperature relatively stable. The body fluids of most invertebrates have about the same osmotic concentration as sea water, so fluid and salt balance are more easily maintained there than in fresh water. **Plankton**, which mainly consists of the microscopic animals and protists that are suspended in the water, provides a ready source of food for many aquatic animals.

Life in the ocean also presents some challenges. Although the continuous motion of water brings nutrients to animals and washes their wastes away, animals must be able to cope with the water's movements and the currents that could sweep them away. Squids, fishes, and marine mammals have evolved as strong swimmers, usually able to direct their movements and maintain their location. However, most invertebrates and young vertebrates cannot swim strongly, and they have adapted in various ways to the tides and currents.

Some sessile animals attach permanently to a stable structure such as a rock. Others burrow in the sand and silt that cover the sea bottom. Many invertebrates have adapted by maintaining a small body size and becoming part of the plankton. As they are tossed about, their food supply continues to surround them.

Some animals are adapted to freshwater habitats

Fewer types of animals make their homes in fresh water than in the ocean because living in this habitat is more difficult. Fresh water is hypotonic to the tissue fluids of animals, so water tends to move into the animal by osmosis. To survive in this habitat, freshwater species must have mechanisms for removing excess water while retaining salts. This process, called *osmoregulation*, requires an expenditure of energy.

Fresh water offers a much less constant environment than sea water. Animals that inhabit fresh water must have adaptations for surviving variations in oxygen content, temperature, turbidity (due to sediments suspended in the water), and even water volume. In addition, fresh water generally contains less food than the sea.

Terrestrial living requires major adaptations

Living on land is even more difficult than living in fresh water, and the evolution of terrestrial animals involved major adaptations. Analyzing the fossil record, many biologists hypothesize that the first air-breathing terrestrial animals were scorpion-like arthropods that came ashore in the Silurian period about 444 mya. The first vertebrates to inhabit terrestrial environments, the amphibians, did not appear until the Devonian period, about 30 million years later.

The chief problem facing all terrestrial organisms is desiccation (drying out). Water is constantly lost by evaporation and is often difficult to replace. A body covering adapted to minimize fluid loss helps solve this problem in many terrestrial animals (**FIG. 30-2**). Location of the respiratory surface deep within the animal also helps prevent fluid loss. Thus, the gills of aquatic animals are typically located externally or near the body surface, but lungs and tracheal tubes of terrestrial animals are typically found deep inside the body.

Reproduction on land also poses challenges to protecting gametes and the developing offspring from desiccation. Aquatic animals typically shed their gametes in the water, where fertilization occurs. Some land animals, including most amphibians, return to the water for reproduction, and their larval forms develop in the water.

The evolution of internal fertilization has permitted many terrestrial animals, including land planarians, earthworms, land snails, insects, reptiles (including birds), and mammals, to meet the desiccation challenge. Because these terrestrial animals transfer sperm from the body of the male directly into the body of the female by copulation, a watery medium continuously surrounds the sperm. Another important adaptation to reproduction on land is the tough, protective shell that surrounds the eggs of many species (see Fig. 30-2). Secreted by the female, this shell protects the developing embryo from drying out. An alternative

Ed. Degginger/Science Source

Figure 30-2 Adaptations to terrestrial life

The tough, horny skin of the green iguana (*Iguana iguana*) has scales and is water resistant. Leathery eggs protect the embryos from drying out.

adaptation for terrestrial reproduction is development of the embryo within the moist body of the mother.

Water has buoyancy that helps support animals that inhabit aquatic environments. Air is less dense than water, and to inhabit the land, animals must have structures, such as a skeletal system and muscles, that support the body. The temperature extremes of terrestrial habitats also present challenges. In later chapters we discuss behavioral and physiological adaptations for maintaining body temperature.

CHECKPOINT 30.2

- What are some advantages of marine environments over freshwater and terrestrial habitats?
- **CONNECT** What are some animal adaptations to the terrestrial environment?

30.3 Animal Evolution

LEARNING OBJECTIVE

- 3 Use current hypotheses to trace the early evolution of animals.

Most biologists agree that animals share a common ancestor with a group of protists known as *choanoflagellates* (see Fig. 26-21). The cells of these colonial flagellates became specialized to perform specific functions, such as movement, feeding, or reproduction. As this division of labor evolved, a colony of flagellates reached the level of cooperation and coordination that qualified it to be considered a single organism, the first animal. The choanoflagellates, fungi, and animals are a monophyletic group known as **opisthokonts**. Recall from Chapter 26 that opisthokonts are characterized by a posterior flagellum on motile cells.

Historically, biologists depended on fossils, similarities in body plan (i.e., structure), and patterns of development to determine evolutionary relationships among various groups of animals. As discussed in Chapter 23, **molecular systematics**, the science that focuses on molecular structure to clarify evolutionary relationships, has provided additional data that are critical in answering questions about phylogeny. Molecular data often confirm hypotheses that were based on morphology (structure).

Complex genomes were apparently present early during animal evolution. Molecular studies suggest that the ancestor of animals had more than 1500 genes not found in other eukaryotes. Some of these genes may be traced to *horizontal gene transfer* from other domains, followed by modification of the genes. Complex genomes have been described in the sea anemone and in other animals that are relatively simple morphologically.

Molecular analyses indicate that the structure of genes that control development, RNA molecules, and many other molecules are very similar among all animal groups that have been studied. According to the *principle of parsimony*, such complex molecules are unlikely to have evolved multiple times (see Chapter 23). Thus, these data support the hypothesis that animals evolved only once. Animals are a monophyletic group.

Molecular systematics helps biologists interpret the fossil record

Because early animals were soft-bodied forms that left few fossils, the evolutionary history of animals has been vigorously debated. The scarcity of fossils has made it difficult to determine the age, rate of divergence, and number of branches of animal groups. In 2009, a research team found fossil traces in an oil field on the Arabian Peninsula that are thought to date back more than 635 million years. The fossil traces are steroids found only in the skeletal structures of certain sponges (demosponges). Before this discovery, the earliest known animal fossils were the *Ediacaran biota* from the **Ediacaran period** (635 mya to 541 mya). These fossils of small, simple animals suggest that sponges, jellyfish, and comb jellies were present during this period (see Fig. 21-9).

Paleontologists have discovered many large, complex animal fossils in Chengjiang, an Early Cambrian (542 mya to 520 mya) fossil site in China, and in the Burgess Shale in British Columbia, a Middle Cambrian fossil site (520 mya to 515 mya). Fossils of most extant phyla (and also many extinct animals) have been found at these sites. The rapid evolution of an amazing variety of body plans during this time is known as the **Cambrian radiation**, or less formally as the **Cambrian explosion** (see Fig. 21-10). The many new body plans that evolved during this time account for many branches of the animal tree.

Studies of large molecular data sets suggest that most animal clades actually diverged over a very long period during the Proterozoic eon (2.5 bya to 541 mya). Thus, the animal phyla that first left fossils during the Cambrian radiation may have evolved several hundred million years *before* they appear in the fossil record. Biologists estimate that certain groups are about twice as old as the oldest fossils found to date. According to this view, the Cambrian radiation was a rapid evolution of new animal body plans among clades that already existed. Perhaps fossils of these early animals remain to be discovered in Proterozoic rocks. Another hypothesis holds that a change in environmental conditions that occurred prior to the Cambrian radiation allowed fossils to form.

Biologists develop hypotheses about the evolution of development

Changes in animal body plans are linked to changes in patterns of embryonic development. Biologists have long used similarities and differences in embryonic development to hypothesize how animal groups are related. Traditionally, biologists depended mainly on structural changes to compare the process of development in various groups.

Researchers focusing on the molecular basis of developmental processes have identified genes that direct the early development of the body plan. They have discovered that many of these genes have been conserved during animal evolution. The same basic set of genes controls early development in all animal groups. Furthermore, the same genes are used in the same ways to regulate development.

Evolutionary developmental biology, sometimes referred to as **Evo Devo**, has become an important approach to studying

animal relationships. Biologists compare molecular events, such as gene regulation during development, in various animal groups.

Recall from Chapter 17 that **Hox genes** are a group of regulatory genes that specify the anterior–posterior axis during development (see Fig. 17-13). The presence and number of *Hox* genes provide insights about evolutionary relationships. These genes have been identified in all the bilateral animal groups that have been studied, suggesting that the last common ancestor of all bilateral animals had similar *Hox* genes. These genes have been identified in a sea anemone (*Nematostella vectensis*), which is a cnidarian. Cnidarians are marine animals, for example, jellyfish, with radial symmetry. This finding suggests that the cnidarians share a common ancestor with the bilateral animals.

Investigators think that the *Hox* gene groups had evolved by the beginning of the Cambrian period. Mutations in *Hox* genes could have resulted in rapid changes in animal body plans. For example, regulation by *Hox* gene groups has been linked with the development of wings or legs. Similarities in molecular development among different animal groups suggest that they had a common ancestor.

CHECKPOINT 30.3

- What was the Cambrian radiation?
- According to the current hypothesis, when did most major groups of animals evolve?
- **CONNECT** How has the discovery of *Hox* genes helped biologists understand animal evolution?

30.4 Reconstructing Animal Phylogeny

LEARNING OBJECTIVES

- 4 Describe how biologists use morphology (including variations in body symmetry, number of tissue layers, and type of body cavity) and patterns of early development to infer relationships among animal phyla.
- 5 Cite specific examples of how data from molecular systematics have confirmed or modified traditional animal phylogeny and identify the three major clades of bilateral animals.

Because some animal body plans have been highly conserved throughout evolutionary history, variations in body plans can provide clues to animal relationships. For example, biologists compare variations in body symmetry, number of tissue layers, types of body cavity, and pattern of development. Biologists also use similarities and differences in embryonic development to infer evolutionary relationships among animal groups. In addition to these traditional methods, researchers now have molecular tools to enhance our understanding of animal phylogeny. Because of technological improvements over the last few decades, comparisons of nucleic acid (DNA and RNA) and protein structure provide critical data for biologists seeking to interpret and reconstruct animal phylogeny.

Animals exhibit two main types of body symmetry

Symmetry refers to the arrangement of body structures in relation to the body axis. Most sponges are not symmetrical, so when a sponge is cut in half, the two halves are not similar to each other. Most other animals exhibit either radial or bilateral body symmetry.

Cnidarians (jellyfish, sea anemones, and their relatives) and adult echinoderms (sea stars and their relatives) have **radial symmetry**. The body has the general form of a wheel or cylinder, and similar structures are regularly arranged as spokes from a central axis (FIG. 30-3a). Multiple planes can be drawn through the central axis, each dividing the organism into two mirror images. An animal with radial symmetry receives stimuli equally from all directions in the environment. Some animals have modified radial symmetry. For example, sea anemones and ctenophores (comb jellies) have *biradial symmetry*, in which parts of the body have become specialized so that only two planes can divide the body into similar halves.

Most animals exhibit **bilateral symmetry**, at least in their larval stages. A bilaterally symmetrical animal can be divided through only one plane (which passes through the midline of the body) to produce roughly equivalent right and left halves that are mirror images (FIG. 30-3b).

As bilateral symmetry evolved, natural selection led to **cephalization**, the development of a head where sensory structures are concentrated. In these groups, concentrations of nerve cells in the head form a brain, and one or two nerve cords extend from the brain toward the rear end of the animal. Bilateral symmetry and cephalization are adaptations for locomotion. The head end of the animal meets its environment first and is best equipped to capture food or respond to danger.

Some definitions of basic terms and directions will help in locating body structures in bilaterally symmetrical animals. The back surface of an animal is its **dorsal** surface; the underside (belly) is its **ventral** surface. **Anterior** (or *cephalic*) means toward the head end of the animal; **posterior**, or *caudal*, means toward the tail end. A structure is said to be *medial* if it is located toward the midline of the body, and it is *lateral* if it is toward one side of the body. For example, the human ear is lateral to the nose. In human anatomy the term *superior* refers to a structure located above some point of reference, or toward the head end of the body. The term *inferior* is used in human anatomy to mean located below some point of reference, or toward the feet.

A bilaterally symmetrical animal has three axes, each at right angles to the other two. Its anterior–posterior axis extends from head to tail. Its dorsal–ventral axis extends from back to belly, and a left–right axis extends from side to side. We can distinguish three planes or sections that divide the body into specific parts. A *sagittal plane* divides the body into right and left parts. A sagittal plane passes from anterior to posterior and from dorsal to ventral. A *frontal plane* divides a bilateral body into dorsal and ventral parts. A *transverse section*, also called a *cross section*, cuts at right angles to the body axis and separates anterior and posterior parts.

(a) **Radial symmetry.** Multiple planes can be drawn through the central axis; each divides the animal into two mirror images.

(b) **Bilateral symmetry.** The head of the animal is its anterior end, and the opposite end is its posterior end. The back of the animal is its dorsal surface, and the belly is its ventral surface. The diagrams illustrate various ways the body can be sectioned (cut) to study its internal structure. A cross (transverse) section divides the body into anterior and posterior parts. A frontal, or longitudinal, cut (lengthwise horizontal) divides the body into dorsal and ventral parts. A sagittal section (lengthwise vertical cut) divides the animal into right and left parts.

Figure 30-3 Radial and bilateral symmetry

Throughout this book, sections of animals are shown to illustrate the structure and arrangement of tissues and organs.

Animal body plans are linked to the level of tissue development

Sponges have several types of cells, but their cells are not organized into **tissues**, which are groups of closely associated, similar cells that work together to carry out specific functions. In the early development of all animals except sponges, cells form layers, called **germ layers**. The outer germ layer, or **ectoderm**, gives rise to the tissues that form the outer covering of the body

as well as to nervous tissue. The inner layer, or **endoderm**, forms the lining of the digestive tube and other digestive structures. These layers develop into specific types of tissues.

Biologists describe cnidarians and ctenophores as **diploblastic** because they have only two germ layers. Other animals are **triploblastic**. They have a third germ layer, the **mesoderm**, which gives rise to most other body structures, including muscles, skeletal structures, and circulatory system (when present).

Most bilateral animals have a body cavity lined with mesoderm

The vast majority of bilateral animals have a fluid-filled body cavity, or **coelom** (pronounced “see’-lum”), between the outer wall of the body and the digestive tube (FIG. 30-4). The flatworms and ribbon worms are exceptions. They are bilateral and triploblastic but have a solid body; that is, they have no body cavity. They are referred to as **acoelomates** (*a-*, “without”; and *coelom*, “cavity”).

Most animals have a body cavity that is completely lined with mesoderm. Such a body cavity is a **true coelom**. An animal with a true coelom is referred to as a **coelomate**. The coelom was one of the most important early animal adaptations. Evolution of the coelom was a critical step in the evolution of larger, more complex animals.

With the evolution of the coelom came a new body design, the **tube-within-a-tube** body plan. The coelom is a space that separates the body wall, the outer tube, from the digestive tube (gut), which is the inner tube. The digestive tube is attached to the body wall at its ends. Typically, the digestive tube has a mouth at one end for taking in food and an anus at the other end for eliminating wastes. Because the coelom separates the muscles of the body wall from those in the wall of the digestive tract, the digestive tube can move food along independently of body movements.

Because it is an enclosed compartment (or series of compartments) of fluid under pressure, the coelom can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid. The hydrostatic skeleton also shapes the body of soft animals. The evolution of various shapes and divisions of the coelom provided the opportunity for animals to become specialized in swimming, crawling, or walking. Animals that can move quickly to capture food or avoid predators are more likely than slower-moving animals to survive.

Evolution of the coelom provided a space where internal organs could develop and function. For example, the pumping action of the heart is possible because of the surrounding space the coelom provides. The fluid-filled coelom also protects internal organs by cushioning them. (Other functions of the coelom will be discussed in Chapter 31.)

Some (typically, small) animals have a body cavity that is not completely lined with mesoderm. This type of body cavity is called a **pseudocoelom** (“false coelom”). Animals

Figure 30-4 Three basic body plans in triploblastic animals

The germ layer from which each tissue was derived is indicated in parentheses. Ectoderm is shown in blue, mesoderm in red, and endoderm in yellow.

with a pseudocoelom, such as nematodes (roundworms) and rotifers, are called **pseudocoelomates**. Because the pseudocoelom appears to have evolved independently in different animal taxa, the presence of a pseudocoelom is not considered a useful characteristic for determining phylogeny. Instead, it is an example of homoplasy. (Recall from Chapters 18 and 23 that the term *homoplasy* refers to similarities that are independently acquired by convergent evolution.)

Bilateral animals form two main clades based on differences in development

Embryonic development begins as the zygote undergoes cleavage, the first several cell divisions of the embryo. During cleavage, the embryo develops into a hollow ball of cells, the blastula. Cells of the blastula undergo **gastrulation**, a process that forms and segregates the three germ layers.

Basic differences in the pattern of early development distinguish two main evolutionary lines of bilateral animals: **protostomes** (pro'-tuh-stomes), assigned to the clade *Protostomia*, and **deuterostomes** (doo'-ter-uh-stomes), assigned to the clade *Deuterostomia*. The protostomes include mollusks (e.g., snails, clams, squids), annelids (e.g., earthworms), arthropods (e.g., crabs, insects), and several other groups. Deuterostomes include the echinoderms (such as sea stars and sea urchins) and chordates (which include the vertebrates).

One important difference in the development of protostomes and deuterostomes is the pattern of cleavage. In many protostomes the early cell divisions are diagonal to the polar axis (the long axis of the embryo), resulting in a somewhat spiral arrangement of cells; any one cell lies between the two cells above or below it (**FIG. 30-5a**). This pattern of division is known as **spiral cleavage**. In **radial cleavage**, characteristic of the deuterostomes, the early divisions are either parallel to the polar axis or at right angles to it. The resulting cells lie directly above or below one another (**FIG. 30-5b**).

In the protostomes the developmental fate of each embryonic cell is typically fixed very early. For example, if the first four cells of an annelid embryo are separated, each cell develops into only a fixed quarter of the larva; this pattern of cleavage is called **determinate cleavage**. In contrast, deuterostomes typically undergo **indeterminate cleavage**. During early cleavage, each cell has the potential of developing into a complete embryo.

For example, if the first four cells of a sea star embryo are separated, each cell can form a complete, although small, larva. If a few cells are removed from a blastula undergoing indeterminate cleavage, other cells compensate, and the embryo develops normally. In contrast, if a few cells are removed from the blastula of an embryo undergoing determinate cleavage, some structure, such as a limb, does not develop.

During gastrulation, a group of cells moves inward, forming a sac that becomes the embryonic gut. The opening to the outside is called the **blastopore**. In most protostomes the blastopore develops into the mouth. The word *protostome* comes from Greek words meaning “first” and “the mouth.” In deuterostomes the blastopore does not give rise to the mouth but generally develops into the anus. A second opening that forms later in development gives rise to the mouth. The word *deuterostome* derives from words meaning “second” and “the mouth.”

Biologists have identified major animal clades based on structure, development, and molecular data

As we have discussed, biologists have long inferred evolutionary relationships among animals based on their structural variations and patterns of development. More recently,

Figure 30-5 Spiral and radial cleavage

The pattern of cleavage can be appreciated by comparing the positions of the purple cells in (a) and (b).

new technology, such as advances in microscopy, cell labeling, and genetics, has helped systematists clarify evolutionary relationships among animal groups. Molecular data have also challenged some traditional conclusions, such as *when* various animal groups diverged in relation to other groups. Such questions continue to be the topic of much debate.

Animals are referred to as *metazoa*. Animals with two or three germ layers (diploblastic or triploblastic) make up the *eumetazoa*. As we have described, some animals exhibit asymmetry (sponges), radial symmetry (cnidarians), or biradial symmetry (ctenophores). The *Bilateria*, the lineage of animals with bilateral symmetry, are triploblastic. (They have three germ layers: ectoderm, endoderm, and mesoderm.) As explained in the last section, biologists classify bilateral animals into protostome and deuterostome clades.

Molecular data show that the protostomes split into two major clades: **Lophotrochozoa** (pronounced “lo-fah-tro-kah-zo’-ah”) and **Ecdysozoa** (pronounced “ek-dah-so-zo’-ah”) (**TABLE 30-1** and **FIG. 30-6** on page 638). Animals assigned to the *Lophotrochozoa* are characterized by (1) a lophophore, a ciliated ring of tentacles surrounding the mouth that serves as a feeding organ; or (2) a type of larva called a *trochophore larva*. The Lophotrochozoa include the flatworms, ribbon worms, mollusks, annelids, and three groups sometimes referred to as the lophophorate phyla.

The name *Ecdysozoa* is derived from the animals in this group molting, a process called *ecdysis*. The Ecdysozoa include the nematodes and arthropods. Note that the phylogeny we have described assigns bilateral animals to three major clades: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

Table 30-1 Overview of the Animal Kingdom

Major Groups and Subgroups	Some Key Characters/Comments
 Poriferans (sponges)  Cnidarians Medusozoans: hydras, jellyfish Anthozoans: corals, sea anemones  Ctenophores (comb jellies)	Collar cells, flagellated cells that trap food; cells loosely associated and do not form true tissues; sponge larvae have flagella and can swim about; poriferans are probably not a monophyletic group Radial symmetry; cnidocytes (stinging cells); polyp and medusa body forms; tentacles surround mouth; mainly marine Biradial symmetry; eight rows of cilia that resemble combs; tentacles with adhesive glue cells; marine predators
PROTOSTOMES: LOPHOTROCHOZOAN CLADE	Bilateral symmetry; triploblastic
 Flatworms (platyhelminths) Free-living planarians Parasitic flukes and tapeworms	Gastrovascular cavity with one opening; no coelom; cephalization
 Nemerteans (ribbon worms)	Proboscis (long, muscular tube that can be everted to capture prey); complete digestive tube; mainly marine carnivores
 Mollusks Chitons Gastropods: snails, slugs, nudibranchs Bivalves: clams, oysters Cephalopods: squids, octopods	Soft body typically covered by dorsal shell; muscular foot; mantle covers visceral mass; most have a radula (belt of teeth)
 Annelids Errantians: marine worms (sandworms, tubeworms) Sedentarians: earthworms, leeches	Segmented body; most have bristles, called setae, that provide traction during crawling
 Lophophorates Brachiopods Phoronids Bryozoans (ectoprocts)	Lophophore (ring of ciliated tentacles around mouth); mainly sessile, marine
 Rotifers (wheel animals)	Crown of cilia at anterior end; microscopic; freshwater and marine

Continued

Segmentation apparently evolved three times

Over millions of years, evolutionary forces acting on the basic animal body plan have produced changes resulting in a remarkable diversity of body forms. One very important innovation has been *segmentation*, a body plan in which certain structures

are repeated, producing a series of body structures and compartments. In some cases, each compartment can be regulated somewhat independently of the others, which allows various parts of the body to become specialized to perform specific functions.

Perhaps the most obvious example of segmentation can be found in earthworms. However, as will be discussed in

Table 30-1 Overview of the Animal Kingdom (*continued*)

Major Groups and Subgroups	Some Key Characters/Comments
PROTOSTOMES: ECDYSOZOAN CLADE  Nematodes (roundworms) Hookworms, trichina worms  Arthropods Myriapods: centipedes and millipedes Chelicerates: horseshoe crabs and spiders Pancrustaceans: crustaceans (lobsters, crabs, barnacles, copepods) and hexapods (insects)	Protostomes with cuticle that is molted and replaced as animal grows Fluid-filled pseudocoelom serves as hydrostatic skeleton; important decomposers; many are predators; some are parasites Segmented; exoskeleton of chitin; paired, jointed appendages; insects and many crustaceans have compound eyes
DEUTEROSTOMES  Echinoderms Crinoids: sea lilies, feather stars Asteroids: sea stars Ophiuroids: basket stars, brittle stars Echinoids: sea urchins, sand dollars Holothuroids: sea cucumbers  Hemichordates (acorn worms)  Chordates Cephalochordates (lancelets) Urochordates (tunicates) Vertebrates: hagfishes, lampreys, cartilaginous fishes, ray-finned fishes, coelacanths, lungfishes, amphibians, reptiles (including birds), mammals	Radial, indeterminate cleavage; pharyngeal slits Water vascular system; tube feet; endoskeleton with spines; larvae bilateral, ciliated; adult, pentaradial symmetry; marine Proboscis, collar, and trunk Notochord; dorsal, tubular nerve cord; postanal tail; endostyle; segmented body Notochord extends from anterior to posterior tip Larvae have chordate characters Vertebral column; cranium; neural crest cells; endoskeleton

the following chapters, arthropods and vertebrates also have segmented body plans. Thus, segmented animals are found within each of the three major clades of bilateral animals. Molecular data suggest that segmentation evolved independently three times and is therefore another example of homoplasy. This view is reflected in the cladogram in Figure 30-6. In each independent origin of segmentation, natural selection apparently acted on many of the same genes (e.g., *Hox* genes).

In this chapter we have briefly discussed characteristics common to animals and the early evolution of animals. We described animal body plans and examined some of the criteria that biologists use to reconstruct phylogenetic relationships. The cladogram shown in Figure 30-6 depicts some of the current hypotheses regarding the relationships among major animal groups, and Table 30-1 summarizes these relationships. In the next two chapters, we survey these animal groups.

In Chapter 31 we describe three groups—sponges, cnidarians, and ctenophores—traditionally viewed as diverging early

in the evolutionary history of animals. We then discuss one of the major clades of animals: the protostomes. Then, in Chapter 32, we discuss the deuterostomes, which include the echinoderms and chordates, the clade to which we humans belong. Many hypotheses are presented in these chapters, and we will discuss many examples of how systematists revise the relationships of the branches of the animal phylogenetic tree in response to new data.

CHECKPOINT 30.4

- How are animals classified based on type of symmetry?
- What are some differences between protostomes and deuterostomes?
- **VISUALIZE** Draw a cladogram illustrating the evolutionary relationships among the three main clades of bilateral animals. How do they differ from one another?

Key Point

Biologists recognize three major clades of bilateral animals: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

Figure 30-6 Evolutionary relationships of animal clades

This cladogram is based on many forms of data, including comparisons of DNA sequences of several genes. Remember that any cladogram of animal relationships is a work in progress. As new data are considered, our understanding of relationships among animal groups changes. Characters labeled on the cladogram indicate when these key traits originated. Note that the simplified cladogram shown in (b) is used as an icon for many figures in Chapters 31 and 32. The animal group being discussed is highlighted in the icon.

CONNECT Using the information indicated by the colored bars above the cladogram in (a), identify which animal groups are assigned to the Ecdysozoa. What shared derived character present in the Ecdysozoa clade is indicated on the cladogram?

Summary: Focus on Learning Objectives

30.1 Animal Characteristics (page 629)

1 Describe several characteristics common to most animals.

- Animals are eukaryotic, multicellular, heterotrophic organisms with cells specialized to perform specific functions. Animals have diverse body plans. The *body plan* is the basic structure and functional design of the body.
- Most animals are capable of locomotion at some time during their life cycle, can respond adaptively to external stimuli, and can reproduce sexually.
- In sexual reproduction sperm and egg unite to form a **zygote**. The zygote undergoes **cleavage**, a series of cell divisions that produce a hollow ball of cells called a **blastula**. Most animals develop into a **larva**, a sexually immature form that may appear and behave differently from the adult. Larvae typically go through **metamorphosis**, a developmental process that converts the immature animal into a juvenile form that grows into an adult.

30.2 Adaptations to Ocean, Freshwater, and Terrestrial Habitats (page 630)

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

- Marine environments have relatively stable temperatures, provide buoyancy, and provide readily available food. Fluid and salt balance are more easily maintained in sea water than in fresh water. Currents and other water movements can be a disadvantage.
- Fresh water offers a less constant environment and less food than sea water. Because fresh water is hypotonic to tissue fluid, animals must osmoregulate.
- Terrestrial animals have adaptations that protect them from drying out and from temperature changes, and that protect their gametes and embryos.

30.3 Animal Evolution (page 631)

3 Use current hypotheses to trace the early evolution of animals.

- Based on molecular data, biologists hypothesize that most animal clades actually diverged over a long period during the Proterozoic eon. During the **Cambrian radiation**, new animal body plans rapidly evolved among clades that already existed.
- Hox genes** control early development in animal groups. These genes had evolved by the beginning of the Cambrian period, and mutations in these genes could have resulted in rapid changes in animal body plans.

30.4 Reconstructing Animal Phylogeny (page 632)

4 Describe how biologists use morphology (including variations in body symmetry, number of tissue layers, and type of body cavity) and patterns of early development to infer relationships among animal phyla.

- Biologists hypothesize that cnidarians (which have **radial symmetry**) and ctenophores (which have **biradial symmetry**) are more closely related to each other than to animals that exhibit **bilateral symmetry**. **Cephalization**, the development of a head, evolved along with bilateral symmetry.

- Biologists have also inferred relationships based on level of tissue development and type of body cavity. Embryonic tissues, called **germ layers**, include the outer layer, **ectoderm**, which gives rise to the body covering and the nervous system; the inner layer, **endoderm**, which lines the gut and other digestive organs; and a middle layer, **mesoderm**, which gives rise to muscle, skeletal structures, and most other body structures.
- In bilateral animals the type of body cavity has been used to classify animals. **Acoelomate** animals have no body cavity, and **coelomate** animals have a *true* coelom, a body cavity completely lined with mesoderm. Some animals have a **pseudocoelom** (literally, a “false cavity”), a body cavity that is not completely lined with mesoderm.

- Two major evolutionary branches of bilateral animals are **protostomes** (mollusks, annelids, and arthropods) and **deuterostomes** (echinoderms and chordates).
 - Protostomes undergo **spiral cleavage**, in which early cell divisions are diagonal to the polar axis. Deuterostomes undergo **radial cleavage**, in which the early cell divisions are either parallel or at right angles to the polar axis, so the cells lie directly above or below one another.
 - Protostomes undergo **determinate cleavage**, in which the fate of each embryonic cell is fixed very early. Deuterostomes undergo **indeterminate cleavage**: early in development each cell has the potential to develop into a complete organism.
 - In protostomes the **blastopore**, the opening from the embryonic gut to the outside, develops into the mouth; in deuterostomes the blastopore typically becomes the anus.
- 5 Cite specific examples of how data from molecular systematics have confirmed or modified traditional animal phylogeny and identify the three major clades of bilateral animals.
- Molecular systematics has confirmed much of animal phylogeny that was originally based on structural characters, including the axiom that animal body plans usually evolved from simple to complex. However, molecular systematics has also provided evidence for exceptions.
 - Based on molecular data, biologists now subdivide the protostomes into two clades: **Lophotrochozoa** and **Ecdysozoa**. The Lophotrochozoa include the flatworms, ribbon worms, mollusks, annelids, rotifers, and animals that have a lophophore, a ciliated ring of tentacles

surrounding the mouth. The Ecdysozoa, animals that molt, include the nematodes and arthropods. The third clade of animals, Deuterostomia, includes the echinoderms, hemichordates, and chordates. These animals have radial, indeterminate cleavage and pharyngeal slits.

Test Your Understanding

Know and Comprehend

- Which of the following is *not* a characteristic of all animals? (a) heterotrophic (b) multicellular (c) eukaryotic (d) presence of a coelom (e) formation of a zygote that undergoes cleavage
- Which of the following is *not* an adaptation to terrestrial living? (a) internal fertilization (b) shell surrounding egg (c) adaptations for maintaining body temperature (d) surface for gas exchange deep in body (e) ability to maintain location
- The Cambrian radiation (a) occurred during the late Cambrian period (b) was a rapid evolution of new animal body plans during the middle Cambrian (c) was a result of prokaryotic and eukaryotic migration to many new regions (d) is supported by the great variety of Ediacaran fossils (e) b and c
- The germ layer that gives rise to the outer covering of the body and the nervous system is the (a) blastula (b) ectoderm (c) gastrula (d) endoderm (e) mesoderm
- Radial symmetry is characteristic of (a) protostomes (b) chordates (c) mollusks (d) cnidarians (e) sponges
- A coelom is a body cavity completely lined with (a) epithelium (b) ectoderm (c) mesoderm (d) endoderm (e) epidermis
- Protostomes are characterized by (a) spiral cleavage (b) indeterminate cleavage (c) an acoelomate body plan (d) radial symmetry (e) a and c
- The evolution of animals (a) followed an orderly progression from simple to complex (b) will be better understood as biologists continue to collect molecular and other types of data (c) has been determined by studying classification (d) began with the cnidarians (e) began with their common ancestor, a protostome
- Which of the following is an example of a deuterostome? (a) lophotrochozoan (b) coral (c) chordate (d) planarian flatworm (e) insect

Apply and Analyze

- VISUALIZE** Label the branches of the diagram.

- Imagine that you discover a new organism in a lake. How would you decide whether it is an animal? What are some characteristics that might contribute to your decision?
- EVOLUTION LINK** Examine the cladogram in Figure 30-6a. Based on the discussion in this chapter, what were some of the types of data that biologists used to determine these phylogenetic relationships?

Evaluate and Synthesize

- EVOLUTION LINK** Suggest and support a hypothesis for the view that segmentation evolved in three different animal clades.
- INTERPRET DATA** Imagine that a biologist discovers evidence that a newly discovered animal evolved from a very early protostome. Where would you place the branch (clade) for that animal on Figure 30-6a?

31 Sponges, Cnidarians, Ctenophores, and Protostomes

In Chapter 30 we introduced the animal kingdom and explored animal phylogeny. We examined how systematists use fossils, morphology, developmental patterns, and molecular data to determine animal relationships. In this chapter we begin with an introduction to the sponges, cnidarians, and ctenophores, groups characterized by asymmetry, radial symmetry, and biradial symmetry, respectively. The phylogeny of these animals is the focus of much current research. Although sponges, cnidarians, and ctenophores are mainly small animals with simple body structures, they are of great ecological importance. They have complex relationships with many other organisms. For example, they are important members of marine food webs and some form symbiotic relationships with other animals. Many provide shelter for other organisms. Corals that produce reefs are among the most ecologically important animals in the world.

Following our discussion of the sponges, cnidarians, and ctenophores, we begin our survey of the bilateral animals, the most familiar and by far the most numerous animals on Earth. More than 99% of animal species belong to the Bilateria. These diverse forms have adapted to life in almost every imaginable habitat in the ocean and in freshwater and terrestrial environments. The Sally Lightfoot crab shown in the photograph is an example of the diverse animals found among the Bilateria.

The remarkable success of the bilateral animals can be attributed to the evolution of adaptations that facilitated food capture, escape from predators, and reproduction. Among their key adaptations are cephalization (formation of a head), a central nervous system, muscles, a coelom, and compartmentalization of the body. Large animals developed body systems for gas exchange,

KEY CONCEPTS

- 31.1** Animals with asymmetry, radial symmetry, or biradial symmetry include sponges, cnidarians (hydras, jellyfish, sea anemones, corals), and ctenophores (comb jellies). Sponges are characterized by collar cells and by loosely associated cells that do not form true tissues; cnidarians are characterized by radial symmetry, two tissue layers, and cells that contain stinging organelles; and ctenophores have biradial symmetry, two tissue layers, eight rows of cilia, and tentacles with adhesive glue cells.
- 31.2** Protostomes are a large monophyletic group that includes two major clades: Lophotrochozoa and Ecdysozoa. The lophotrochozoans include the annelids (segmented worms), mollusks, and several smaller groups.
- 31.3** The ecdysozoans include the nematodes (roundworms) and arthropods (centipedes and millipedes; horseshoe crabs and spiders; crustaceans and insects). The remarkable biological success of the arthropods can be attributed to the evolution of complex body plans and life cycles, including their exoskeleton, segmentation, specialized jointed appendages, ability to fly (among insects), and metamorphosis.

PHOTO: Sally Lightfoot crab (*Grapsus grapsus*). This fast-moving crab lives and hides among the rocks along the Western coast of North and South America. It has a varied diet, grazing on red and green algae as well as scavenging and preying on smaller animals. Photographed in the Galápagos Islands. Charles Martin

waste disposal, and internal transport of nutrients, respiratory gases, wastes, and other materials.

Recall that based on molecular data, pattern of early development, and other data, biologists divide the bilateral animals into two main groups: protostomes and deuterostomes. The protostomes form two clades: Lophotrochozoa and Ecdysozoa. In this chapter we focus on the innovations in body plans, phylogenetic relationships, and life histories of several phyla of these two clades.

31.1 Sponges, Cnidarians, and Ctenophores

LEARNING OBJECTIVES

- 1 Identify important characteristics of poriferans.
- 2 Identify distinguishing characteristics of cnidarians, describe their two main clades, and list animals that belong to each clade.
- 3 Identify characteristics of ctenophores.

Recall from Chapter 30 that based on available evidence, animals and choanoflagellates (a group of unicellular and colonial protists) share a common choanoflagellate ancestor. Many biologists assign sponges to a basal group, **Parazoa** (*para*, “alongside”; and *zoa*, “animals”). This classification is based on the asymmetry and simple body plan of sponges. The cells of sponges are loosely associated and do not form true tissues. Other animals have true tissues and are classified as **Eumetazoa** (*eu*, “true”; *meta*, “later”; and *zoa*, “animals”). Thus, these biologists divide the animal kingdom into two major animal groups: Parazoa and Eumetazoa. Despite some controversy, most systematists consider sponges to be the oldest group of animals.

Based on molecular data, biologists hypothesize that sponges are a polyphyletic group. There is some evidence that at least one group of sponges (calcareous sponges) became simplified as they evolved from animals with more complex body plans.

Sponges have collar cells and other specialized cells

Sponges, or **poriferans**, are aquatic, mainly marine animals that are most abundant in warm waters. Their name, *Porifera* (paw-rif'-er-ah), means “to have pores.” This name aptly describes these animals, whose bodies are perforated by tiny holes. Biologists have identified more than 8800 species of sponges. They range in size from a few millimeters to more than a meter in height and diameter (loggerhead sponges). Many sponges are asymmetrical, but they vary in shape from flat, encrusting growths to balls, cups, fans, or vases. Living sponges may be brightly colored—green, orange, red, yellow, blue, or purple—or they may be white or drab (FIG. 31-1). Some species are inhabited by symbiotic bacteria or algae that give them color.

Although they are multicellular and can be large, sponges function much like choanoflagellates. These protists are characterized by a single flagellum surrounded by a collar of microvilli

(see Fig. 26-21). Sponges have flagellate cells called **collar cells**, or **choanocytes** (ko-an'-uh-sites), which are strikingly similar to choanoflagellates.

Sponge larvae have flagella and can swim about. Adult sponges attach to some solid object and have long been described as sessile. However, biologists have observed adults of several species moving slowly (about 4 mm per day), perhaps by the cumulative movement of cells along the sponge's lower surface.

Although sponges are multicellular, their cells are loosely associated and do not form true tissues. However, a division of labor exists among the several types of cells that make up the sponge, with certain cells specializing in nutrition, support, contraction, or reproduction. Many sponge cells are extremely versatile and can change form and function.

Collar cells make up the inner layer of certain sponges. Each cell is equipped with a tiny collar surrounding the base of the flagellum. The collar is an extension of the plasma membrane and consists of microvilli. Collar cells create the water current that brings food and oxygen to the cells and carries away carbon dioxide and other wastes. Collar cells also trap and phagocytize food particles. Together, the collar cells of some sponges can pump a volume of water equal to the volume of the sponge each minute!

Sponges have three types of canal systems through which water circulates. In the simple *asconoid* canal system, the beating flagella of collar cells create a current that pulls water through hundreds of tiny pores, called *ostia*. Specialized tubelike cells, called *porocytes*, form the pores. These cells regulate the diameter of the pores by contracting. Water passes into the central cavity, or **spongocoel** (spon'-jo-seel) (not a digestive cavity), and then flows out through the sponge's open end, the **osculum** (os'kyuh-lum). The asconoid system is illustrated in Figure 31-1.

In the *syconoid* system, water enters through canals lined by collar cells. Most types of sponges have a *leuconoid* system. The body wall is extensively folded, and complex systems of canals provide increased surface area for food capture. *Epidermal cells* form the outer layer of the sponge and line the canals. The canals lead into small chambers that are lined with collar cells.

The skeletal framework of a sponge can be both rigid and fibrous. Between the outer and inner cell layers, the sponge body has a gelatin-like layer, the *mesohyl*, which is supported by slender skeletal spikes, or **spicules** (spik'-yuls). *Amoeboid cells*, which wander about in the mesohyl, secrete the spicules. The spicules are made of calcium carbonate or of silica. The fibrous part of the sponge skeleton consists of *spongin*, a form of collagen.

Most sponges are *suspension feeders*, adapted for trapping and eating whatever food is suspended in the water. As water circulates through the body, bacteria, algae, and other organic particles are trapped along the sticky collars of the collar cells. Thus, the collars *filter* the suspended food particles out of the water. Suspension feeders that filter the suspended food are known as *filter feeders*. Food particles are either digested within the collar cell or transferred to an amoeboid cell for digestion. The amoeboid cell transports nutrients to epidermal cells. Undigested food passes out through the osculum and is simply eliminated into the water. Researchers have discovered several species of carnivorous sponges that trap prey on very small hooks on their bodies. These sponges lack collar cells.

Figure 31-1 Sponge structure

(a) Tube sponges (*Spinosella plicifera*) from the Caribbean attached to the coral reef substrate. **(b)** Sponge cut to expose its organization. This sponge has an asconoid type of canal system.

Gas exchange and excretion of wastes depend on diffusion into and out of individual cells. Although cells of the sponge can react to stimuli, sponges do not have specialized nerve cells and so cannot react as a whole. However, electrical signals have been identified in certain glass sponges. Behavior appears limited to basic metabolic necessities such as capturing food and regulating the flow of water through the body.

Sponges reproduce both asexually and sexually. In asexual reproduction, a small fragment or bud may break free from the parent sponge and give rise to a new sponge. Such fragments may attach to the parent sponge, forming, or becoming part of, a colony. Most sponges are **hermaphrodites**, meaning that the same individual can produce both eggs and sperm. Some of the amoeboid cells develop into sperm cells and others into egg cells. However, hermaphroditic sponges usually produce eggs and sperm at different times, and they cross-fertilize with other sponges. They release mature sperm into the water, which are taken in by other sponges of the same species.

Fertilization and early development take place within the jellylike mesohyl. Zygotes develop into flagellate larvae that leave the parent along with the stream of outflowing water.

After swimming for a while, a larva finds a solid object, attaches to it, and settles down to a sessile life.

Sponges have a remarkable ability to repair themselves when injured and to regenerate lost parts. When the cells of a sponge are separated experimentally, they recognize one another and their place in the whole and aggregate to re-form a complete sponge. Researchers have discovered that some sponges produce antibacterial and other compounds that may be effective against MRSA (see Chapter 25) and cancer cells.

There are three main groups of sponges: the *calcareous sponges* have spicules composed of calcium carbonate, whereas the *glass sponges* and the *demosponges* have spicules of silicon. About 95% of living sponges are demosponges. In some of the demosponges, spicules are bound together by spongin. Some demosponges do not have spicules. These soft sponges have been used for thousands of years as bath sponges and for cleaning. Unfortunately, as a result of overharvesting, bath sponges are now in short supply.

Sponges play significant roles in marine habitats. Larger species are important structural components in both shallow and deep water, providing homes to many species of annelids, crustaceans, and echinoderms. Sponges also serve as food for some invertebrates, fish, and sea turtles.

Cnidarians have unique stinging cells

More than 10,000 species of **cnidarians** (ni-dah'-ree-ans) have been described. Most are marine. The radially symmetrical cnidarian body is organized as a hollow sac with the mouth and surrounding tentacles located at one end. Some cnidarians live a solitary existence, whereas many others, such as corals, form colonies.

Cnidarians have two body shapes: polyp and medusa (**FIG. 31-2**). The **polyp** form, represented by *Hydra*, typically

has a dorsal mouth surrounded by tentacles. In the **medusa** (pl., *medusae*), or jellyfish form, the mouth is located in the lower concave, or oral, surface; the convex upper surface is the **aboral** surface. Some cnidarians have the polyp shape during one stage of their life cycle and the medusa form during another stage. The Portuguese man-of-war and some other cnidarians consist of colonies of many individuals, some of which are polyps and others medusae.

Cnidarians get their name from specialized cells, called **cnidocytes** (from a Greek word meaning “nettle cells”), that contain stinging organelles. Cnidocytes are located mainly in the epidermis, especially on the tentacles. The cnidocytes contain stinging “thread capsules,” called **nematocysts** (**FIG. 31-3**). Each cnidocyte has a small, projecting trigger (*cnidocil*) on its outer surface and a coiled, hollow thread inside. We can compare the cnidocyte to a loaded gun, ready to fire. When stimulated by touch or certain chemicals dissolved in the water, the nematocyst fires its thread. Some types of nematocyst threads are sticky. Others are long and coil around prey. A third type bears barbs or spines that can inject a protein toxin. This toxin paralyzes prey animals, such as small crustaceans.

Cnidarians use their tentacles to capture prey and push it into the mouth. The mouth leads into the **gastrovascular cavity**,

(b) Undischarged and discharged nematocyst. The cnidocil, or trigger, is a mechanoreceptor that discharges the nematocyst when it senses contact with an object.

Figure 31-3 Nematocysts

When cnidarian stinging cells (cnidocytes) are stimulated, the nematocyst discharges, ejecting a thread that may entangle or penetrate the prey. Some nematocysts secrete a toxic substance that immobilizes the prey.

where digestion takes place. The mouth is the only opening into the gastrovascular cavity and so must serve for both ingestion of food and expulsion of undigested material. Gas exchange and excretion occur by diffusion. The body wall is thin enough that no cell is far from the surface.

More highly organized than sponges, cnidarians are diploblastic; that is, they have two definite tissue layers. The ectoderm gives rise to the outer epidermis, a protective layer covering the body. The endoderm gives rise to the inner *gastrodermis*, which lines the gastrovascular cavity and

functions in digestion. These thin layers are separated by a thick, jellylike **mesoglea**, which is mainly acellular.

The nerve cells of a cnidarian form a **nerve net** that connects sensory cells in the body wall to contractile cells and gland cells. An impulse set up by one sensory cell passes in all directions more or less equally. Nerve cells are not organized to form a brain or nerve cord. In some types of medusae, sense organs are positioned around the edge of the body. The sense organs include simple “eyes,” called eyespots; organs of balance (statocysts); and chemoreceptors (cells that sense certain chemicals).

Both the epidermis and gastrodermis have cells specialized to contract. (However, they are not true muscle cells). Contractile fibers in the epidermal cells are arranged lengthwise, and those in the gastrodermis are arranged in a circular pattern. These two sets of contractile cells act on the water-filled gastrovascular cavity, forming a **hydrostatic skeleton**. This skeleton supports the body and allows movement. By contracting one set of contractile cells or the other, the hydra can shorten, lengthen, or bend its body (see Fig. 40-2).

Based on fossil and molecular evidence, systematists divide the cnidarians into two major clades that split during their early evolution. Clade Medusozoa consists of the hydrozoans, scyphozoans, and cubozoans. Clade Anthozoa includes the sea anemones, corals, and sea fans (**TABLE 31-1**).

Most medusozoans develop a medusa form during their lifetime

Hydrozoans include hydras and *hydroids*, such as *Obelia* and the Portuguese man-of-war. Although not really typical, the solitary *Hydra* is the cnidarian that beginning biology students most often study (**FIG. 31-4**). To the naked eye, *Hydra* looks like a bit of frayed string. This tiny hydrozoan is found in freshwater ponds. Because it has a remarkable ability to regenerate, biologists named *Hydra* after the multiheaded monster of Greek mythology that could grow two new heads for each head cut off. When *Hydra* is cut into several pieces, each piece can regenerate all the missing parts and become a whole animal.

Hydra lives in fresh water and typically attaches to a rock, aquatic plant, or detritus by a disc of cells at its base. Hydras reproduce asexually by budding during periods when

Table 31-1 Major Clades of Cnidaria

Clade and Representative Animals	Characteristics
MEDUSOZOANS	
Hydrozoans <i>Hydra</i> , <i>Obelia</i> , Portuguese man-of-war	Mainly marine, but some freshwater species; alternation of polyp and medusa stages in most species (<i>Hydra</i> has only polyp form); some form colonies
Scyphozoans Jellyfish, cubozoans (“box jellyfish”)	Mainly marine; typically inhabit coastal waters; free-swimming medusa most prominent form; polyp stage often reduced
ANTHOZOANS Sea anemones, corals, sea fans	Marine; solitary or colonial polyps; no medusa stage in most; gastrovascular cavity divided by partitions into chambers, increasing area for digestion

Figure 31-4 *Hydra*, a freshwater hydrozoan

environmental conditions are optimal. However, they differentiate as males and females and reproduce sexually in the fall or when pond water becomes stagnant. The zygote may become covered with a shell that protects it through the winter or until conditions become more favorable.

Many hydrozoans form colonies consisting of hundreds or thousands of individuals. A colony begins with a single polyp that reproduces asexually by budding. However, instead of separating from the parent, the bud remains attached and eventually forms additional buds. Several types of individuals may develop in the same colony, some specialized for feeding, some for reproduction, and others for defense.

Some marine hydrozoans are remarkable for their alternation of sessile polyp and motile medusa stages. The life cycle of the colonial marine hydrozoan *Obelia* illustrates alternation of polyp and medusa stages (FIG. 31-5). In *Obelia*, polyps reproduce asexually by budding, whereas the medusae reproduce

sexually, using meiosis to produce gametes. Both polyp and medusa are diploid; only sperm and eggs are haploid.

In both *scyphozoans* and *cubozoans*, the medusa is the dominant body form. Jellyfish medusae are generally larger than hydrozoan medusae. They have a thick, viscous mesoglea that gives firmness to the body. In *scyphozoans* the polyp stage is small and inconspicuous or may even be absent. The largest jellyfish, *Cyanea*, may be more than 2 m (6.5 ft) in diameter and have tentacles 30 m (98 ft) long. These orange and blue “monsters,” among the largest invertebrates, can cause painful stings to swimmers in the North Atlantic and Pacific Oceans.

When viewed from above, cubozoans have a square shape. Known as “box jellyfish,” they have four tentacles, or groups of tentacles. These fast-swimming jellyfish have complex eyes that form blurred images, and they actively hunt for prey. Some cubozoan species, referred to as *sea wasps*, produce extremely toxic venom. Found in waters off the northern Australian coast, the sea wasp *Chironex fleckeri* has long tentacles that can extend more than 3 m (10 ft). This sea wasp produces one of the deadliest venoms in the animal kingdom. Its venom contains toxins that can stun or kill fish and other prey. These toxins can also

cause respiratory failure and cardiac arrest in humans. Fatalities are mainly associated with severe stings caused by contact with tentacles over a large area of the body. Interestingly, sea turtles feed on box jellyfish, apparently unaffected by their venom.

Anthozoans are polyps *Anthozoans*, which include the sea anemones and corals, are either individual or colonial polyps. There is no free-swimming medusa stage. The polyp produces eggs and sperm, and the fertilized egg develops into a small, ciliated **planula larva**. This larval form may swim to a new location before attaching to develop into a polyp.

Anthozoans differ from hydrozoans in that a series of vertical partitions partially divides the gastrovascular cavity into connected chambers. The partitions increase the surface area for digestion, enabling an anemone to digest an animal as large as a crab. Although corals can capture prey,

(a) LM of *Obelia*. Some polyps have tentacles and are specialized for feeding, whereas others are specialized for reproduction.

(b) Life cycle of *Obelia*.

Figure 31-5 *Obelia*, a marine colonial hydrozoan

many tropical species depend for nutrition on photosynthetic dinoflagellates (*zooxanthellae*). These golden brown dinoflagellates live within cells lining the coral's digestive cavity (see Chapter 26 and Fig. 54-12). The relationship between coral and zooxanthellae is symbiotic and mutually beneficial. The coral supplies the dinoflagellates with a place to live and with waste products such as ammonia. The dinoflagellates use the ammonia to make nitrogen compounds for both partners and provide the coral with carbon compounds and oxygen.

In warm, shallow seas, much of the bottom is covered with coral or anemones, many of them brightly colored. Coral reefs consist of colonies of millions of corals and of algae (mainly coralline red algae). Living colonies occur only in the uppermost regions of such reefs, adding their own skeletons to the forming rock. Coral reefs are among the most productive of all ecosystems, rivaling tropical rain forests in species diversity (see Fig. 56-21). A single reef can serve as home for more than 3000 species of fishes and other marine organisms, and an estimated one-fourth of all marine species depend on coral reefs.

Many species of reef-building corals are endangered and are at increased risk for extinction. Human activities are responsible for much of the damage. Global climate change, which results from production of carbon dioxide and other greenhouse gases, causes ocean temperatures to rise (see Chapter 57). When stressed by the hot water, coral cells expel the symbiotic dinoflagellates that inhabit their cells. The coral then appears white, or “bleached.” This process is known as **coral bleaching** (FIG. 31-6). Without their dinoflagellates, coral become malnourished and die if conditions do not improve.

Figure 31-6 Bleached staghorn coral

Global climate change (caused by human activities) is a major cause of coral bleaching. This staghorn coral (*Acropora*) was photographed off Heron Island on the Great Barrier Reef off the coast of Australia.

Other factors leading to the decline of coral reefs include acidification of the ocean caused by increase in carbon dioxide in the atmosphere, pollution, disease, smothering coral with the silt washed downstream from clear-cut forests, and overharvesting. At the time of this writing, damaging, widespread coral bleaching was continuing for the third year in a row. In 2016, 90% of the coral of Australia's Great Barrier Reef was affected by bleaching, killing more than 20% of the reef's coral.

Comb jellies have adhesive glue cells that trap prey

The fragile, luminescent *comb jellies* are marine animals known as **ctenophores** (ten'-oh-forz). Approximately 150 species of ctenophores have been described. Some are as small as a pea; others are larger than a tomato. Ctenophores are an important part of the plankton.

The outer surface of a ctenophore bears eight rows of cilia that resemble combs (**FIG. 31-7**). Ctenophores are biradially symmetrical, meaning you could obtain equal halves by cutting through the

body axis in two different ways. The ctenophore body plan is somewhat similar to that of a cnidarian medusa in that ctenophores have a type of radial symmetry, feeding tentacles, and two cell layers separated by a thick, jellylike mesoglea.

Some ctenophores have two tentacles. Their tentacles are equipped with adhesive glue cells. When prey comes in contact with the tentacle, the glue cells burst open, releasing sticky threads that trap the prey. Ctenophores do not have the stinging nematocysts characteristic of the cnidarians. Also unlike cnidarians, the ctenophore digestive system has a mouth for food intake at one end and two anal pores for the egestion of water and particles that are indigestible at the other end.

Ctenophores have a nervous system that includes a network of nerve cells and a sensory organ called a "statocyst" that coordinates beating of the cilia in the combs. The coordinated beating of the cilia moves the animal through the water. The statocyst also functions in balance and helps the animal orient itself.

Because of their similarities, biologists classify ctenophores near the cnidarians. However, their development is different, and their digestive cavity has openings at both ends. The similarities between ctenophores and cnidarians may be a result of convergent evolution from living in a similar environment, the ocean. Where, then, do the ctenophores belong on our cladogram? As systematists gather new data, the position of the ctenophores on the animal tree will become clearer.

- In what ways do cnidarians differ from sponges?
- **VISUALIZE** Sketch the major events of the life cycle of *Obelia*.
- In what ways are ctenophores like cnidarians? In what ways are they different?

WaterFrame/Alamy Stock Photo

Figure 31-7 Ctenophore (comb jelly)

Ctenophores are free-swimming, bioluminescent hermaphrodites capable of self-fertilization. The warty comb jelly (*Mnemiopsis leidyi*; also known as the sea walnut) refracts light so that it appears to have colors running down the track of its cilia. *Mnemiopsis* is also bioluminescent, and flashes when disturbed. This animal is a predator that consumes crustaceans, eggs and larvae of fishes, and zooplankton.

31.2 The Lophotrochozoa

LEARNING OBJECTIVES

- 4 Summarize what is known about the phylogeny of the lophotrochozoans and cite the adaptive advantages of having a coelom and of cephalization.
- 5 Identify distinguishing characteristics of flatworms and nemerteans, and describe the main groups of flatworms, giving examples of animals that belong to each.
- 6 Describe the main characteristics of mollusks and of the four clades of mollusks discussed, giving examples of each group.
- 7 Describe the principal characteristics of annelids and of the two clades of annelids discussed, giving examples of each group.
- 8 Describe the distinguishing characteristics of the lophophorates and of the rotifers.

We begin our discussion of the bilateral animals with the **Lophotrochozoa**, one of the two major clades of protostomes. The Lophotrochozoa includes the flatworms (platyhelminths), rotifers (wheel animals), nemerteans (ribbon worms), mollusks, annelids (segmented worms), and the lophophorate phyla (see Fig. 30-6). Recall from Chapter 30 that the name *Lophotrochozoa* comes from two important characters of some animals in this clade: (1) the *lophophore*, a ciliated ring of tentacles surrounding the mouth in three small groups of animals; and (2) the *trochophore larva*, a type of larva that characterizes two major groups: the mollusks and annelids.

Most lophotrochozoans have **bilateral symmetry**, at least in their larval stages. They are **triploblastic**; that is, they have three definite tissue layers. In addition to the outer epidermis derived from ectoderm and an inner endodermis derived from endoderm, lophotrochozoans have a middle tissue layer that develops from mesoderm.

Most lophotrochozoans have a true **coelom** and a *tube-within-a-tube body plan* (see Chapter 30). Most coelomate animals have well-developed circulatory, excretory, and nervous systems. Many internal organs are suspended within folds of the tissue lining the coelom and can move independently of the outer body wall. In addition, the coelom provides space for the gonads to develop. During the breeding season of many animals, such as birds, the gonads enlarge within the coelom as they fill with ripe gametes.

In some animals, fluid within the coelom helps transport materials such as food, oxygen, and wastes. Cells bathed by the coelomic fluid can exchange materials with it. The cells receive nutrients and oxygen from the coelomic fluid and excrete wastes into it. Some coelomates have excretory structures that remove wastes directly from the coelomic fluid.

Animals that move about typically have an elongated body with definite anterior and posterior ends. They exhibit **cephalization**, the evolution of a head with a concentration of sense organs at the anterior end. A simple brain and paired sense organs are concentrated in

the “head” region. An animal with a front end generally moves forward. With a concentration of sense organs in the part of the body that first meets its environment, the animal can actively search for food, shelter, and mates or can detect enemies quickly.

Flatworms are bilateral acoelomates

Platyhelminths (plat-ee-hel'-minths), or *flatworms*, are soft-bodied animals that left few fossils to provide clues to their evolutionary history. Their flat, elongated bodies are solid; that is, they are **acoelomate** (have no body cavity). Historically, biologists considered flatworms to be the simplest bilaterally symmetrical, triploblastic animals. However, it is unclear whether the Platyhelminthes evolved from ancestors that possessed a body cavity.

Most of the 20,000 or so species of flatworms belong to a clade called Rhabditophora. We can assign the rhabditophorans to four groups: Turbellarians are free-living flatworms that include planarians and their relatives. They are considered a paraphyletic group. Trematodes and monogeneans include the flukes, which are either internal or external parasites. Cestodes are tapeworms, which as adults are intestinal parasites of vertebrates (**TABLE 31-2**). These parasitic groups are considered a monophyletic group of rhabditophorans.

Flatworms typically have a simple **nervous system**. The brain consists of two masses of nervous tissue, called **ganglia**, in the head region. In many species the ganglia connect to two nerve cords that extend the length of the body. This nervous system is sometimes referred to as a “ladder-type nervous system” because a series of nerves connects the cords like the rungs of a ladder (see Fig. 42-2). Sense organs include simple “eyes,” called eyespots, organs of balance (statocysts), and numerous chemoreceptors over their bodies for locating food and mates.

Table 31-2 Major Groups of Platyhelminths (Largest Clade: Rhabditophorans)

Group and Representative Animals	Characteristics
FREE-LIVING	
Turbellarians Planarians	Mainly free-living; marine, freshwater, and terrestrial; body covered by ciliated epidermis; typically predatory on other invertebrates
PARASITIC	
Trematodes, monogeneans Flukes	Parasites with a wide range of vertebrate and invertebrate hosts; may require intermediate hosts; adults have suckers for attachment to host
Cestodes Tapeworms	Parasites of vertebrates; complex life cycle; usually with one or two intermediate hosts; larval host may be invertebrate; typically have suckers and sometimes hooks for attachment to host; eggs produced within proglottids, which are shed; no digestive or nervous systems

Flatworms have no organs for circulation or gas exchange. Gas exchange depends largely on diffusion through the body wall. The activities of some organs are coordinated and form simple organ systems, such as the digestive and nervous systems. As in the cnidarians, the digestive system is a gastrovascular cavity with only one opening, a mouth. The gastrovascular cavity is often extensively branched.

Parasitic flatworms—flukes and tapeworms—are highly adapted to and modified for their parasitic lifestyle. They have suckers or hooks for holding on to their hosts. The bodies of those that live in digestive tracts resist the digestive enzymes secreted by their hosts. Many have complicated life cycles and produce large numbers of eggs. Other adaptations include the loss of certain structures such as sense organs. Tapeworms have also lost the digestive system.

Turbellarians are free-living flatworms Most turbellarians are free-living flatworms. They inhabit marine, freshwater, and terrestrial habitats. Turbellarian flatworms typically have a muscular pharynx that takes in food and is connected with a branching gastrovascular cavity. They have a simple brain, multiple eyespots, and other sensory organs in the head; **protonephridia**, structures that function in osmoregulation (fluid balance) and metabolic waste disposal (excretion); and reproductive organs.

Planarians are turbellarian flatworms found in ponds, quiet streams, and moist terrestrial habitats throughout the world. One common genus of American planarians, *Dugesia*, contains aquatic worms that reach about 15 mm (0.6 in.) in length. They have what appear to be crossed “eyes” and flapping lateral projections called **auricles** (FIG. 31-8). The auricles actually serve as organs of chemoreception, which is important in locating food.

Most planarians are predators, capable of capturing and killing very small animals. Their digestive system consists of a single opening (the mouth); a tubelike, muscular **pharynx** (the first portion of the digestive tube) and a branched gastrovascular cavity. Many planarians evert (turn inside out) their pharynx out of their mouth and release digestive enzymes onto their captured prey. The liquefied tissues of the prey are then swept by ciliary action into the gastrovascular cavity. The branches of the gastrovascular cavity distribute the nutrients throughout the body of the flatworm. Because planarians lack an anus, digestive wastes leave the body through the mouth.

Some metabolic wastes leave the body by diffusion. Other metabolic wastes are excreted by the protonephridia, blind tubules that end in **flame cells**. The flame cells are collecting cells equipped with cilia. The beating of the cilia channels waste through the system of tubules and eventually out of the body through excretory pores. Osmoregulation and protonephridia are discussed further in Chapter 48 (see Fig. 48-2).

Figure 31-8 The common planarian, *Dugesia*

Planarians reproduce either asexually or sexually. In asexual reproduction an individual constricts its body and divides into two planarians. Each regenerates its missing parts. Sexually, these animals are hermaphrodites. During the warm months of the year, each is equipped with a complete set of male organs and female organs. Two planarians come together in copulation and exchange sperm cells so that their eggs are cross-fertilized.

Flukes parasitize other animals Although their body plan generally resembles that of the free-living flatworms, the *flukes*, trematodes and monogeneans, have structures, such as hooks and suckers, for attachment to their host. Flukes also have extremely prolific reproductive organs.

Flukes that are parasitic in humans include blood flukes, which are widespread in tropical areas of the world, and liver flukes, which are common in Asia, particularly in areas where humans use their own feces for fertilizing crops. Blood flukes of the genus *Schistosoma* cause the human disease schistosomiasis,

the second most debilitating parasitic disease in the world. (Malaria is the first.) An estimated 250 million people are infected, most of them children. The worms live in blood vessels for many years and can damage the liver and kidneys.

Both blood flukes and liver flukes go through complicated life cycles involving several different forms. There is an alternation of sexual and asexual stages as well as parasitism on one or more intermediate hosts, such as snails and fishes (FIG. 31-9). The aquatic snails that serve as intermediate hosts thrive in ponds, rice paddies, and the marshy areas that develop when dams are built.

Tapeworms inhabit the intestine of vertebrates Adult members of the more than 5000 species of cestodes live as parasites in the intestine of probably every kind of vertebrate, including humans. Tapeworms are long, flat, ribbonlike animals strikingly specialized for their parasitic mode of life. The body consists of a *scolex* for attachment to a host and a long chain of segments called *proglottids*. The scolex is equipped

Figure 31-9 Life cycle of the blood fluke (*Schistosoma*)

The LM shows an adult male enfolding a smaller female.

Figure 31-10 Scolex of a tapeworm

The small tapeworm (*Acanthocirrus retrisrostris*) reaches maturity in the intestine of wading birds that eat barnacles. The color-enhanced SEM shows the pistonlike cluster of hooks that can be withdrawn into the head or thrust out and buried in the host's tissue. You can see two of the four powerful suckers beneath the hooks.

with suckers, and sometimes hooks, that enable the parasite to attach to the host's intestine (FIG. 31-10).

The reproductive adaptations and abilities of tapeworms are extraordinary. Each proglottid is an entire reproductive machine equipped with both male and female reproductive organs. A single proglottid contains up to 100,000 eggs. Because an adult tapeworm may have as many as 2000 segments, its reproductive potential is staggering. A single tapeworm can produce 600 million eggs per year! Proglottids farthest from the scolex contain the ripest eggs; these segments are shed from the host's body along with the feces.

A tapeworm has no mouth or digestive system. Digested food from the host is absorbed across the worm's body wall. Tapeworms also lack well-developed sense organs. Some tapeworms have complex life cycles,

spending their larval stage within the body of an intermediate host and their adult life within the body of a different, final host. **FIGURE 31-11** illustrates the life cycle of the beef tapeworm, which can infect humans when they eat undercooked beef containing the larvae.

Nemerteans are characterized by their proboscis

The **nemerteans** (neh-mur'-tee-uns) include the ribbon worms, a relatively small group of about 1200 species of free-living animals (FIG. 31-12). Most burrow in marine sediments, but a few species inhabit deep sea water, fresh water, or damp soil. Many nemerteans are predators, feeding on crustaceans and annelids. Nemerteans have long, narrow bodies, either cylindrical or flattened, ranging in length from 1 mm to more than 30 m (100 ft). Some are a vivid orange, red, or green, with black or colored stripes.

Their most remarkable organ, the *proboscis*, is a long, hollow, muscular tube that can be rapidly everted from the anterior end of the body. Used to capture prey, the sticky proboscis can be wrapped around a small animal. In some species the proboscis is sharp, and in various species it secretes toxic fluid that immobilizes prey. The proboscis is a *derived character* that distinguishes nemerteans from all other invertebrate groups. Because of this character, these animals are sometimes called *proboscis worms*.

Nemerteans have no heart; blood is circulated by contractions of muscular blood vessels and by movements of the body. The chamber surrounding the proboscis is a

Figure 31-11 Life cycle of the beef tapeworm, *Taenia saginata*

(a) Ribbon worm (*Lineus*) from the Pacific coast of Panama.

(b) Lateral view of a typical nemertean. Note the complete digestive tract that extends from mouth to anus.

Figure 31-12 Nemerteans (ribbon worms)

coelomic space known as a *rhynchocoel*. It develops in the embryo as the coelom does in coelomate protostomes (see Chapter 30). However, it differs in position and function from the coelom of other animals. Biologists view the rhynchocoel as a remnant of the coelom of a coelomate ancestor. Because of its presence and recent molecular evidence, biologists classify nemerteans with the lophotrochozoans. Nemerteans evolved from a coelomate animal and became simpler over time.

Mollusks have a muscular foot, visceral mass, and mantle

The **mollusks** include clams, oysters, snails, slugs, octopuses, and the largest of all the invertebrates, the giant squid, which averages 9 to 16 m (about 30 to 53 ft) in length, including its tentacles. More than 100,000 living species and 35,000 fossil species (second only to the arthropods in number) have been described. Here we discuss chitons, gastropods, bivalves, and cephalopods—four of the eight recognized clades. We illustrate representatives of these clades in **FIGURE 31-13** and describe them in **TABLE 31-3**.

Although most mollusks are marine, many snails and clams live in fresh water, and some species of snails and slugs inhabit the land. Mollusks probably evolved early in the history of the protostome clade, soon after the evolution of the

coelom but before the origin of the segmented body that is characteristic of annelids. Although mollusks vary widely in outward appearance, most share six basic characteristics:

1. A soft body, usually covered by a dorsal shell composed mainly of calcium carbonate.
2. A broad, flat, muscular foot, located ventrally, which is used for locomotion.
3. The body organs (*viscera*) are concentrated as a **visceral mass** located above the foot.
4. The dorsal body wall forms a pair of folds called the **mantle**. The mantle is a thin sheet of tissue that generally overhangs the visceral mass, forming a mantle cavity. The mantle may contain glands that secrete a shell. The mantle cavity contains gills or a lung.
5. A rasplike (rough) structure called a **radula**, which is a belt of teeth in the mouth region. (The radula is not present in clams or their relatives, which are filter feeders.)
6. A coelom, generally reduced to small compartments around certain organs, including the heart and excretory organs (*metanephridia*). The main body cavity is typically a **hemocoel**, a space containing blood (see the following discussion of open circulatory systems). The hemocoel is not a coelom.

Mollusks have all the organ systems typical of complex animals. The digestive system is a tube, often coiled, consisting of a

mouth, buccal cavity (mouth cavity), esophagus, stomach, intestine, and anus. The mollusk radula, located within the buccal cavity, projects out of the mouth and shows variation in structure among species related to feeding behaviors. In herbivorous species the radula is used to scrape algae from the surface of rocks or to remove tissue from live plants. The radulas of predatory mollusks may be used to inject toxins into prey, drill holes in the shells of prey animals, or rip apart flesh held in the beaks of cephalopods.

Most mollusks have an **open circulatory system** in which the blood, called **hemolymph**, bathes the tissues directly. The heart pumps blood into a single blood vessel, the aorta, which may branch into other vessels. Eventually, blood flows into a network of large spaces called *sinuses*, bringing the blood into direct contact with the tissues. This network makes up the hemocoel, or blood cavity. From the sinuses, blood drains into vessels that conduct it to the gills, where it is recharged with oxygen. After passing through the gills, the blood returns to the heart. Thus, blood flow in a mollusk follows this pattern:

heart → aorta → smaller blood vessels → blood sinuses (hemocoel) → blood vessels to gills → heart

In open circulatory systems, blood pressure tends to be low, and tissues are not very efficiently oxygenated. Because most mollusks are slow-moving animals with low metabolic rates, this type of circulatory system is adequate. The active cephalopods (the class that includes the squids and octopuses) have a **closed circulatory system** in which blood flows through a complete circuit of blood vessels.

Chitons are sluggish marine animals with shells composed of eight overlapping plates. The blue lined chiton (*Tonicella undocerulea*) inhabits rocks along the North American Pacific coast. It grazes on algae.

The broad, flat foot of the gastropod is an adaptation to its mobile lifestyle. The mystery snail (*Pomacea bridgesi*) inhabits fresh water and can be found burrowing in the mud.

The compressed body of the horse-neck clam (*Tresus capax*) is adapted for burrowing in the North Pacific mud. Its shell grows to about 20 cm (8 in.) in length.

The squid body is streamlined for swimming. To avoid being seen by potential predators, a squid can change color to blend with its background. This northern short-fin squid (*Illex illecebrosus*) grows to a mantle length of up to about 31 cm (about 1 ft). It inhabits the North Atlantic Ocean.

Figure 31-13 The mollusk body plan

Table 31-3 Four Clades of Mollusks

Clade and Representative Animals	Characteristics
CHITONS	Marine; dorsal shell consisting of eight separate transverse plates; head reduced; broad foot used for locomotion; uses radula to scrape algae and other small organisms off rocks
GASTROPODS Snails, slugs, nudibranchs	Marine, freshwater, or terrestrial; coiled shell in many species; torsion of visceral mass; well-developed head with tentacles and eyes; predators, herbivores, and detritus feeders
BIVALVES Clams, oysters, mussels	Marine or freshwater; body laterally compressed; two-part shell hinged dorsally; hatchet-shaped foot; filter feeders
CEPHALOPODS Squids, octopuses	Marine; foot modified into tentacles, usually bearing suckers; well-developed eyes; closed circulatory system; predatory

Most marine mollusks pass through one or more larval stages. The first stage is typically a **trochophore larva**, a free-swimming, top-shaped larva with two bands of cilia around its middle (FIG. 31-14). In many mollusks (gastropods such as snails and bivalves such as clams) the trochophore larva develops into a **veliger larva**, which has a shell, foot, and mantle. The veliger larva is unique to the mollusks.

Chitons appear to be similar to ancestral mollusks *Polyplocophorans* (pol-ee-plah-kof-o-rans; meaning “many plates”) are *chitons*, marine animals with flattened bodies (see Fig. 31-13a). Their most distinctive feature is a shell composed of eight separate but overlapping dorsal plates. The head is reduced, and there are no eyes or tentacles.

Chitons inhabit rocky intertidal zones, using a broad, flat foot to move and to hold on firmly to rocks. By pressing its mantle against the substratum and lifting the inner edge of the mantle, a chiton can produce a partial vacuum. The resulting suction lets the animal adhere powerfully to its perch. Using the radula for grazing, chitons scrape algae and other small organisms off rocks and shells.

Figure 31-14 A trochophore larva

The first larval stage of a marine mollusk, the trochophore larva, is also characteristic of annelids. Just above the mouth, a band of ciliated cells functions as a swimming organ and, in some species, collects suspended food particles.

Gastropods are the largest group of mollusks The *gastropods*—the snails, slugs, conchs, sea slugs, and their relatives—are the largest and most diverse group of mollusks (see Fig. 31-13b). In fact, with more than 70,000 extant species, gastropods constitute the second-largest class in the animal kingdom, second only to insects. Most gastropods inhabit marine waters, but others make their homes in brackish or fresh water or on land. We think of snails as having a single, spirally coiled shell into which they can withdraw the body, and many do. However, other gastropods, such as limpets, have shells like flattened dunce caps. Still others, such as garden slugs and the beautiful marine slugs known as *nudibranchs*, have no shell at all (FIG. 31-15).

Many gastropods have a well-developed head with tentacles. Two simple eyes may be located on stalks that extend from the head. The gastropod uses its broad, flat foot for creeping. Most land snails do not have gills. Instead, the mantle is highly vascularized and functions as a lung. Biologists describe these garden snails and slugs as pulmonate (“having a lung”).

Torsion, a twisting of the visceral mass, is a unique feature of gastropods. This twisting is unrelated to the coiling of the shell. As the bilateral larva develops, one side of the visceral mass grows more rapidly than the other side. This uneven growth rotates the

Figure 31-15 Nudibranch (*Felimare tricolor*)

Nudibranchs (known as sea slugs) are a group of gastropods that have no shell. They feed on sponges and other small marine animals. The species shown here is small, about 25 mm, but other nudibranchs grow to about 600 mm (24 in.).

Figure 31-16 Torsion in a gastropod

As the bilateral larva develops, the visceral mass twists 180 degrees relative to the head. The digestive tube coils, and the anus becomes relocated near the mouth.

visceral mass. The visceral mass and mantle twist permanently up to 180 degrees relative to the head. As a result, the digestive tract becomes somewhat U-shaped, and the anus comes to lie above the head and gill (FIG. 31-16). Subsequent growth is dorsal and usually in a spiral coil. Torsion limits space in the body, and typically the gill, excretory organ (metanephridium), and gonads are absent on one side. Some biologists hypothesize that torsion is an adaptation that protects the head by allowing it to enter the shell first during withdrawal from potential predators. Without torsion, the foot would be withdrawn first.

Most bivalves are filter feeders The *bivalves* include clams, oysters, mussels, scallops, and their relatives (see Fig. 31-13c). Typically, the soft body is laterally compressed and completely enclosed by a two-part shell that hinges dorsally and opens ventrally (FIG. 31-17). This arrangement allows the hatchet-shaped foot to protrude ventrally for locomotion and for burrowing in mud. The two parts, or *valves*, of the shell are connected by an elastic ligament. Stretching of the ligament opens the shell. Large, strong adductor muscles attached to the shell permit the animal to close its shell.

Figure 31-17 Internal anatomy of a clam

The two shells of a bivalve hinge dorsally and open ventrally.

The inner, pearly layer of the bivalve shell is made of calcium carbonate secreted in thin sheets by the epithelial cells of the mantle. Known as *mother-of-pearl*, this material is valued for making jewelry and buttons. Should a bit of foreign matter lodge between the shell and the mantle, the epithelial cells covering the mantle secrete concentric layers of calcium carbonate around the intruding particle. Many species of oysters and clams form pearls in this way.

Some bivalves, such as oysters, attach permanently to the substrate. Others burrow slowly through rock or wood, seeking protected dwellings. The shipworm, *Teredo*, a clam that damages dock pilings and other marine installations, is just looking for a home. A few bivalves, such as scallops, swim rapidly by clapping their two shells together with the contraction of a large adductor muscle (the part of the scallop that humans eat).

Clams and oysters are filter feeders that trap food particles suspended in sea water. They take water in through an extension of the mantle called the *incurrent siphon*. As the water passes over the gills, mucus secreted by the gills traps food particles in the stream of water. Cilia move the food to the mouth. Water and digestive wastes leave by way of an *excurrent siphon*. An oyster can filter more than 30 L (about 32 qt) of water per hour! As filter feeders, bivalves have no need for a radula, and indeed they are the only group of mollusks that lack this structure.

Cephalopods are active predators In contrast with most other mollusks, members of class *Cephalopoda* (meaning “head-foot”) are fast-swimming predators (see Fig. 31-13d). The mouth of cephalopods is surrounded by tentacles, or arms: 8 in octopuses, 10 in squids, and as many as 90 in the chambered nautilus. The large cephalopod head has well-developed eyes that form images. Although they develop differently, their complex eyes are structurally similar to vertebrate eyes and function in much the same way. Octopuses have no shell, and the shells of squid, located inside the body, are greatly reduced.

The *nautilus* is a cephalopod with a coiled shell consisting of many chambers built up over time. Each year, the animal lives in the newest and largest chamber of the series. *Nautilus* secretes a mixture of gases similar to air into the other chambers. By regulating the amount of gas in the chambers, the animal controls its buoyancy in the ocean.

The tentacles of squids, octopuses, and cuttlefish are covered with suckers for seizing and holding prey. In addition to a radula, the mouth has two strong, horny beaks used to kill prey and tear it to bits. The thick, muscular mantle is fitted with a funnel-like *siphon*. By filling the cavity with water and ejecting it through the siphon, cephalopods achieve forceful jet propulsion. Squids and cuttlefish have streamlined bodies adapted for efficient swimming.

In addition to speed, a cephalopod has two other adaptations that facilitate escape from its predators, which include certain whales, seals, large fish, and other cephalopods. It can confuse the enemy by rapidly changing colors. By expanding and contracting *chromatophores*, cells in the skin

that contain pigment granules, a cephalopod can display an impressive variety of mottled colors. Another defense mechanism is its *ink sac*, which produces a thick, black liquid the animal releases in a dark cloud when alarmed. While its enemy pauses, temporarily blinded and confused, the cephalopod escapes. The ink inactivates the chemical receptors of some predators, making them incapable of detecting their prey.

Octopuses feed on crabs and other arthropods, catching and killing them with a poisonous secretion of their salivary glands. During the day, an octopus usually hides among the rocks; in the evening, it emerges to hunt for food. Its motion is incredibly fluid, giving little hint of the considerable strength in its eight arms.

Small octopuses survive well in aquariums and have been studied extensively. Because octopuses are relatively intelligent and can make associations among stimuli, researchers have used them as models for studying learning and memory. Their highly adaptable behavior more closely resembles that of the vertebrates than the more stereotypic patterns of behavior observed in other invertebrates (see Chapter 52).

Annelids are segmented worms

Annelids (an'-eh-lids) are segmented worms with bilateral symmetry and a tubular body that may be partitioned into more than 100 ringlike segments. More than 17,000 species of annelids have been identified. They inhabit terrestrial, marine, and freshwater environments.

The term *Annelida* (from a Latin word meaning “little rings”) refers to the series of rings, or segments, that make up the annelid body. Both the body wall and many of the internal organs are segmented. Some structures, such as the digestive tract and certain nerves, extend the length of the body, passing through successive segments. Other structures, such as excretory organs, are repeated in each segment. In polychaetes and earthworms, segments are separated from one another internally by transverse partitions called **septa** (sing., *septum*).

An important advantage of **segmentation** is that it facilitates locomotion. The coelom is divided into segments, and each segment has its own muscles. This arrangement allows the animal to elongate one part of its body while shortening another part. The annelid's hydrostatic skeleton is important in movement. Polychaetes and earthworms have bristlelike structures called **setae** (sing., *seta*) located on each segment. Setae provide traction as the worm moves along by alternating contraction of its longitudinal and circular muscles. In earthworms, setae consist mainly of chitin.

The annelid nervous system typically consists of a ventral nerve cord and a simple brain consisting of a pair of ganglia. Each segment has a pair of ganglia and lateral nerves. Annelids have a large, well-developed coelom; a closed circulatory system; and a complete digestive tract extending from mouth to anus. Respiration is *cutaneous*—that is, through the skin—or by gills. Typically, a pair of excretory tubules called **metanephridia** is located in each segment (described in Chapter 48).

Behavioral patterns that ensure fertilization have evolved in many annelid species. By responding to certain rhythmic variations, or cycles, in the environment, nearly all the females

and males of a given species release their gametes into the water at the same time. For example, more than 90% of reef-dwelling *Palolo* worms of the South Pacific shed their eggs and sperm within a 2-hour period on the same night of the year. The posterior portion of the *Palolo* worm, loaded with eggs or sperm, breaks off from the rest of the body. It comes to the surface and bursts, releasing its gametes. This mass reproductive event occurs in October or November at the beginning of the last lunar quarter. Local islanders gather great numbers of the swarming polychaetes, which they bake or eat raw.

Traditionally, annelids were assigned to three main groups: the polychaetes, a group of mainly marine worms; the earthworms and their relatives; and the leeches (**TABLE 31-4** and **FIG. 31-18**). Recent phylogenetic analyses indicate, however, that the annelids form two large clades: Errantia and Sedentaria.

Errantians include polychaete worms Many **errantians** are mobile marine worms that swim freely in the sea. Others crawl or burrow in the mud near the shore or in crevices of rocks or coral reefs. Still other errantians are part of the plankton and are important in marine food chains. Some errantians live in tubes they secrete or make by cementing bits of shell and sand together with mucus. Giant tube worms have been found in deep vents in the floor of the Pacific Ocean (see *Inquiring About: Life without the Sun* in Chapter 55).

Each body segment typically bears a pair of paddle-shaped appendages called **parapodia** (sing., *parapodium*) that function in locomotion and in gas exchange. Each of these fleshy structures bears many stiff setae. Most errantians have a well-developed head with eyes and antennae. The head may also be equipped with sensory tentacles and palps (feelers). Errantians develop from free-swimming trochophore larvae similar to those of mollusks.

Sedentarians include earthworms and leeches Compared to the errantian species, most **sedentarians** are less mobile. Some live in tubes and use their gills or tentacles to filter food from the water.

Table 31-4 Clades of Annelids

Clade and Representative Animals	Characteristics
ERRANTIANs	
Sandworms, tubeworms	Mainly marine; each segment bears a pair of parapodia with many setae; well-developed head; separate sexes; trochophore larva
SEDENTARIANs	
Earthworms	Terrestrial and freshwater worms; few setae per segment; lack well-developed head; hermaphroditic
Leeches	Most are blood-sucking parasites that inhabit fresh water; appendages and setae absent; prominent muscular suckers

Figure 31-18 Three types of annelids

Earthworms help maintain fertile soil More formally known as *oligochaetes*, earthworms live almost exclusively in fresh water and in moist terrestrial habitats. More than 5000 species have been identified. Earthworms lack parapodia, have only a few bristles per segment (the term *oligochaete* means “few bristles”), and lack a well-developed head. All oligochaetes are hermaphroditic.

Lumbricus terrestris, a common earthworm, can reach 20 cm (8 in.) or more in length. Its body has more than 100 segments, separated externally by grooves that indicate the internal position of the septa (FIG. 31-19). The earthworm’s body is somewhat protected from drying by a thin, transparent **cuticle** secreted by the cells of the epidermis. Mucus secreted by gland cells of the epidermis forms an additional protective layer over the body surface. The body wall has an outer layer of circular muscles and an inner layer of longitudinal muscles.

Earthworms eat living and dead plant material. Some species feed mainly above the soil surface and other species feed within the ground, consuming mineral soil particles and organic matter. As earthworms burrow and feed, they move nutrients through the soil. Their activity creates pathways for oxygen and water movement, which greatly increases suitability of the soil for plant growth.

Earthworms process their meals in complex digestive systems. Food is swallowed through the muscular **pharynx** and passes through the **esophagus**, modified to form a thin-walled *crop* where food is stored. Food then passes through a thick-walled, muscular *gizzard*, where food is ground to bits by sand grains consumed along with the meal. The rest of the digestive system is a long, straight *intestine* that chemically digests food and absorbs nutrients. Wastes pass out of the intestine to the exterior through the **anus**.

The efficient closed circulatory system consists of two main blood vessels that extend longitudinally. The dorsal blood vessel, just above the digestive tract, collects blood from vessels in the segments. The dorsal vessel functions as a heart: it contracts to pump blood anteriorly. Five pairs of blood vessels surrounding the esophagus, referred to as *aortic arches*, conduct blood from the dorsal to the ventral blood vessel. Small vessels branch from it and deliver blood to the various structures in each segment and to the body wall. Within these structures, blood flows through tiny capillaries before returning to the dorsal blood vessel.

Gas exchange takes place through the moist skin. Oxygen is transported by *hemoglobin*, a respiratory pigment in the blood. The excretory system consists of paired metanephridia, repeated in almost every segment of the body, that remove nitrogenous wastes from the coelomic fluid.

The nervous system consists of a pair of *cerebral ganglia* (a simple brain) just above the pharynx and a subpharyngeal ganglion just below the pharynx. A ring of nerve fibers connects these ganglia. From the lower ganglion, a ventral nerve cord extends beneath the digestive tract to the posterior end of the body. A pair of fused ganglia is present in each segment along the nerve cord. Nerves extend laterally from the ganglia to the muscles and other structures of that segment. The ganglia coordinate muscle contractions of the body wall, allowing the worm to creep along.

Like most annelids, earthworms are hermaphroditic. During copulation, two worms, headed in opposite directions, press their ventral surfaces together. These surfaces become glued together by the thick mucous secretions of each worm’s *clitellum*, a thickened ring of epidermis. Sperm are then exchanged and stored in the *seminal receptacles* (small sacs) of the other worm. A few days later, each clitellum secretes a membranous cocoon containing a sticky fluid. As the cocoon is slipped forward, eggs are laid in it. Sperm are added as the cocoon passes over the openings of the seminal receptacles. As the cocoon slips free over the worm’s head, its openings constrict so that a spindle-shaped capsule is formed. The fertilized eggs develop into tiny worms within this capsule. This reproductive pattern is an adaptation to terrestrial life; the cocoon protects the delicate gametes and young worms from drying out.

Many leeches are blood-sucking parasites Leeches are members of a group called *Hirudinida*. Most leeches inhabit fresh water, but some live in the sea or in moist areas on land.

Figure 31-19 Body plan of an earthworm
(Reproductive structures are not shown.)

Some leeches are nonparasitic predators that capture small invertebrates such as earthworms and snails. However, about 75% of the known species of leeches are blood-sucking parasites. Leeches differ from other annelids in having neither setae nor parapodia.

Leeches have muscular suckers at both the anterior and posterior ends of their body. Most parasitic leeches attach themselves to a vertebrate host and bite through the skin (FIG. 31-20). They suck out a quantity of blood, which is stored in pouches in the digestive tract. *Hirudin*, an anticoagulant secreted by glands in the crop, ensures leeches a full meal of blood. In 31 minutes, a leech can suck out as much as 10 times its own weight in blood! Some leeches feed only about twice each year because they digest their food slowly over several months.

Leeches have been used since ancient times for drawing blood from areas swollen by poisonous stings and bites. During the 19th century, they were widely used to remove “bad blood,” thought to be the cause of many diseases. Leeches are sometimes used in modern medicine to remove excess fluid and blood that accumulate within body tissues as a result of injury, disease, or surgery (see Fig. 31-20b). The leech attaches its sucker near the site of injury, makes an incision, and secretes hirudin. The hirudin prevents the blood from clotting and dissolves clots that already exist.

The lophophorates are distinguished by a ciliated ring of tentacles

With a few exceptions, **lophophorates** are marine animals adapted for life on the ocean floor. These coelomates are distinguished by their *lophophore*, a ring of ciliated tentacles that surrounds the mouth. The *lophophore* is an adaptation for capturing suspended particles in the water. Lophophorates do not have a distinct head.

The three lophophorate groups are Brachiopoda, Phoronida, and Bryozoa (also known as Ectoprocta). *Brachiopods*, or lampshells, are solitary marine animals that inhabit cold water. Until the mid-19th century, they were thought to be mollusks because they are suspension feeders that superficially resemble clams and other bivalve mollusks. Their body is enclosed between two shells and has a mantle and mantle cavity (FIG. 31-21a). However, brachiopods differ from bivalve mollusks in that the shells are dorsal and ventral rather than lateral; each shell is symmetrical about the midline, and the two shell valves are typically of unequal size.

Brachiopods attach to the substrate by a long stalk. The action of cilia on the lophophore brings water with suspended food into the slightly opened shell. Although there are now only about 325 living species, brachiopods were abundant and diversified during the Paleozoic era. Paleobiologists have described about 12,000 fossil species.

Figure 31-20 Leeches

Only about 20 extant species of *phoronids* are known. They are wormlike, sessile animals found in coastal marine sediments. Adult phoronids secrete chitinous tubes in which they live (FIG. 31-21b). They extend their lophophores from their tubes for feeding. Phoronids vary in length from 2 cm to more than 20 cm (less than 1 in. to about 8 in.), but they are only 1 to 3 mm in diameter.

Bryozoans, also known as *ectoprocts* or “moss animals,” are microscopic aquatic animals that form sessile colonies by asexual budding (FIG. 31-21c). Each colony can consist of millions of individuals and can extend in length up to about 31 cm (about 1 ft). The colonies typically appear plantlike, but some have the appearance of coral. Approximately 4500 living species are known.

Biologists continue to debate the evolutionary position of the lophophorates. They were traditionally considered a monophyletic group and, based on certain structural similarities, a sister group to the deuterostomes. However, the lophophorate groups also have several morphological characters that

suggest a relationship with the lophotrochozoans. Although their phylogeny is still uncertain, based on molecular data (18S rDNA nucleotide sequences), the lophophorate phyla are currently classified as Lophotrochozoa.

Rotifers have a crown of cilia

Rotifers, or “wheel animals,” are among the less familiar invertebrates. Although no larger than many protozoa, these aquatic, microscopic animals are multicellular with complex organ systems. Most of the 2000 described

species inhabit fresh water, but some live in marine environments or damp soil. Rotifers are important in cycling nutrients in aquatic ecosystems. These animals do not have a true coelom and were formerly classified as pseudocoelomates. Current evidence suggests that rotifers evolved from animals with a true coelom, and we classify them as lophotrochozoans.

Rotifers have a characteristic crown of cilia on their anterior end. The cilia beat rapidly during swimming and feeding, giving the appearance of a spinning wheel (FIG. 31-22; also see Fig. 20-1). Rotifers feed on tiny organisms suspended in the stream of water drawn into the mouth by the cilia. A muscular organ posterior to the mouth grinds the food. The complete digestive tract ends in an anus through which wastes are eliminated.

Rotifers have a nervous system with a “brain” and sense organs, including eyespots. Protonephridia with flame cells remove excess water from the body and may also excrete metabolic wastes.

Biologists have discovered that rotifers, like some other animals with a pseudocoelom, are “cell constant,” meaning that each member of a given species has exactly the same number of cells. Indeed, each part of the body has a precisely fixed number of cells arranged in a characteristic pattern. Cell division does not take place after embryonic development, and mitosis cannot be induced. Growth results from an increase in cell size. Do you think that rotifers could develop cancer? One of the challenging research problems of our time is to discover the difference between such nondividing cells and the dividing cells of other animals.

Another interesting characteristic of rotifers is their ability to survive very dry conditions and temperature extremes. These animals can remain in a dormant state for months or years. When conditions become favorable, they recover and become active once again.

CHECKPOINT 31.2

- What are some advantages of cephalization and a coelom?
- **CONNECT** On what basis have biologists classified nemerteans as lophotrochozoans?
- **CONNECT** How does the lifestyle of a gastropod differ from that of a cephalopod? Identify adaptations that have evolved in each for its particular lifestyle.
- What are two distinguishing characteristics for each of the following: flatworms, mollusks, and annelids?

31.3 The Ecdysozoa

LEARNING OBJECTIVES

- 9 Summarize what is known about the phylogeny of the ecdysozoans.
- 10 Describe characteristics of nematodes and identify four parasitic nematodes.
- 11 Describe six key characteristics of arthropods, summarize proposed phylogeny of arthropods, and distinguish among arthropod clades; give examples of animals that belong to each group.
- 12 Identify adaptations that have contributed to the biological success of insects.

The **Ecdysozoa** include the nematodes (roundworms) and arthropods, animals characterized by a **cuticle**, a noncellular body covering secreted by the epidermis. The name *Ecdysozoa* refers to the process of **ecdysis**, or **molting**, which is characteristic of animals in this group. During ecdysis, an animal sheds its outer covering (e.g., cuticle, exoskeleton, or skin), which is then replaced by the growth of a new one. The taxonomic validity of the Ecdysozoa has been supported by many types of data, including molecular data.

Roundworms are of great ecological importance

Nematodes (nem'-uh-todes), or *roundworms*, play key ecological roles as decomposers, parasites, and predators of smaller organisms. Many soil nematodes eat bacteria. Nematodes are numerous and are widely distributed in soil and in marine and freshwater sediments. More than 25,000 species have been described, and many more remain to be discovered. The nematodes rival the insects in number of individuals. A spadeful of soil may contain thousands of these mainly microscopic worms, which thrash around, coiling and uncoiling. Greater understanding of soil nematode diversity and ecology will contribute to solving some important agricultural problems. *Caenorhabditis elegans*, a free-living soil nematode, is an important model research organism for biologists studying the genetic control of development (see Chapter 17).

The elongated, cylindrical, thread-like nematode body is pointed at both ends and covered with a tough, flexible cuticle (FIG. 31-23). Secreted by the underlying epidermis, the thick cuticle gives the nematode body shape and offers some protection. The epidermis is unusual in that it does not consist of distinct cells.

Nematodes have a fluid-filled pseudocoelom that serves as a

hydrostatic skeleton. It transmits the force of muscle contraction to the enclosed fluid. Movement of fluid in the pseudocoelom is also important in transporting nutrients and wastes. Like ribbon worms, nematodes exhibit bilateral symmetry, a complete digestive tract, three definite tissue layers, and definite organ systems. However, they lack specific circulatory structures. The sexes are usually separate, and the male is generally smaller than the female.

Although most nematodes are free-living, others are important parasites in plants and animals. More than 50 species of roundworms are human parasites, including *Ascaris*, hookworms, pinworms, and the trichina worm. The common intestinal parasite *Ascaris* spends its adult life in the human intestine, where it ingests partly digested food (FIG. 31-24). *Ascaris* is a white worm up to 25 cm (10 in.) long. Like most parasites, it has remarkable reproductive adaptations that ensure survival within hosts. A mature female may produce as many as 200,000 eggs per day!

Hookworms attach to the lining of the intestine and suck blood, potentially causing serious tissue damage and blood loss. *Pinworms* are the most common worms found in children. The tiny pinworm eggs are often ingested by eating with hands contaminated with them. The *trichina worm* lives inside a variety of animals, including pigs, rats, and bears. Humans typically become infected by eating undercooked, infected meat. Larvae encyst in skeletal muscle and nervous tissue. Filarial nematodes are small, threadlike parasitic worms that are spread among hosts by the bites of insects. Members of this group cause elephantiasis in humans. The dog heartworm infects cats, dogs, and their relatives.

Arthropods are characterized by jointed appendages and an exoskeleton of chitin

Arthropods (ar'-thro-pods) are the most biologically successful group of animals. More than 80% of all known animals are arthropods! They are more diverse and live in a greater range of habitats than the members of any other animal group. More than one million species have been described, and biologists

Figure 31-23 LM of a free-living nematode

This unidentified aquatic nematode is shown among the cyanobacterium *Oscillatoria*, which it eats.

Figure 31-24 The roundworm *Ascaris*

(a) Note the complete digestive tract that extends from mouth to anus. (b) This cross section through *Ascaris* shows the tube-within-a-tube body plan. The protective cuticle that covers the body helps this parasite resist host defenses.

predict millions more will be identified. The following adaptations have greatly contributed to their success:

1. The arthropod body, like that of the annelid, is segmented. *Segmentation* is important from an evolutionary perspective because it provides the opportunity for specialization of body regions. In arthropods, groups of segments are specialized to perform particular functions. Segments differ in shape, muscles, or the appendages they bear.
2. A hard **exoskeleton**, composed of chitin and protein, covers the entire body and appendages. The exoskeleton serves as a coat of armor that protects against predators and helps prevent excessive loss of moisture. It also supports the underlying soft tissues. Arthropods move effectively because distinct muscles attach to the inner surface of the exoskeleton and operate the joints of the body and appendages.

A disadvantage of the exoskeleton is that it is non-living, and the arthropod periodically outgrows it. Recall that *molting* is the process of shedding an old exoskeleton,

which is then replaced by a larger one. The shed exoskeleton represents a net metabolic loss, and molting also leaves the arthropod temporarily vulnerable to predators.

3. **Paired, jointed appendages**, from which this group gets its name (*arthropod* means “jointed foot”), are modified for many functions. They serve as swimming paddles, walking legs, mouthparts for capturing and manipulating food, sensory structures, or organs for transferring sperm.
4. The nervous system, which resembles that of the annelids, consists of a “brain” (cerebral ganglia) and a ventral nerve cord with ganglia. In some arthropods successive ganglia may fuse. Arthropods have a variety of very effective sense organs. Many have organs of hearing and **antennae** that sense taste and touch. Most insects and many crustaceans have **compound eyes** composed of many light-sensitive units called **ommatidia** (see Fig. 43-17). The compound eye can form an image and is especially adapted for detecting movement.

Arthropods have an *open circulatory system*. A dorsal, tubular heart pumps **hemolymph** into a dorsal artery, which may branch into smaller arteries. From the arteries, hemolymph flows into large spaces that collectively make up the hemocoel. Eventually, hemolymph re-enters the heart through openings, called *ostia*, in its walls.

The exoskeleton presents a barrier to diffusion of oxygen and carbon dioxide through the body wall. Specialized respiratory systems have evolved for gas exchange. Most aquatic arthropods have gills that function in gas exchange. In contrast, many terrestrial forms have a system of internal branching air tubes called **tracheae**, or **tracheal tubes** (see Fig. 46-1b). Other terrestrial arthropods have platelike *book lungs* (see Fig. 46-1d).

The arthropod digestive system is a tube similar to that of earthworms. Excretory structures vary somewhat among groups. The coelom is small and filled chiefly by the organs of the reproductive system.

Arthropod evolution and classification are controversial Two groups of animals once thought to be closely related to arthropods are the onychophorans and the tardigrades (FIG. 31-25). Like arthropods, onychophorans and tardigrades have a thick cuticle and must molt to grow. The body is segmented in all three groups, and all have legs, claws, and a ventral nervous system. These animals all have an open circulatory system, and their coelom is reduced to a hemocoel.

The caterpillar-like *onychophorans*, known as velvet worms, have paired appendages, but these are not jointed. As in arthropods, their jaws are derived from appendages. *Tardigrades*, known as “water bears,” were thought to be the sister taxon of the arthropods. These tiny animals (typically less than 1 mm in length) have short, unjointed, clawed legs (see Fig. 2-11). At this time, the relationships of the onychophorans and tardigrades to the arthropods remain unclear.

Arthropod fossils have been identified dating back to the Proterozoic eon. Early in their evolutionary history, more than 540 million years ago (mya), arthropods diverged into several groups. Arthropods evolved rapidly during the Cambrian radiation, as evidenced by many diverse fossils in the Burgess Shale and other ancient sites.

(a) **Onychophoran.** Note the soft segmented body and series of non-jointed legs. Extant onychophorans live in humid forests, but many extinct species inhabited the ocean.

(b) **Tardigrades.** Commonly known as water bears, tardigrades normally live in moist habitats, such as thin films of water on mosses. Most are less than 1 mm long.

Figure 31-25 Onychophorans and tardigrades

In this edition, based on molecular and other data, we classify the arthropods as belonging to three clades: myriapods, chelicerates, and pancrustaceans (TABLE 31-5). However, as you study the following sections, bear in mind that arthropod systematics is a work in progress. Both the relationship of arthropods to other protostomes and the relationships among arthropods continue to be topics of lively debate.

Trilobites were early arthropods Among the earliest arthropods to evolve, *trilobites* inhabited shallow Paleozoic seas more than 500 mya. These arthropods, which have been

extinct for about 250 million years, lived on the sea bottom and filtered mud to obtain food. Most ranged from 3 to 10 cm (about 1 to 4 in.), but a few reached almost 1 m (39 in.) in length.

Covered by a hard, segmented exoskeleton, the trilobite body was a flattened oval divided into three parts: an anterior head bearing a pair of antennae and a pair of compound eyes, a thorax, and a posterior abdomen (FIG. 31-26). At right angles to these divisions, two dorsal grooves extended the length of the animal, dividing the body into a median lobe and two lateral lobes. (The name *trilobite* derives from this division of the body into three longitudinal parts.) Each segment had a pair of segmented **biramous appendages**, that had two jointed branches extending from their base. In trilobites each appendage consisted of an inner walking leg and an outer branch with gills.

The clade Myriapoda includes the centipedes and millipedes Myriapods are a monophyletic group characterized by unbranched appendages called **uniramous appendages**, jawlike mandibles, and a single pair of antennae. Centipedes (*Chilopoda*) and millipedes (*Diplopoda*) are terrestrial and are typically found beneath stones or wood in the soil in both temperate and tropical regions. Both centipedes and millipedes have a head and an elongated trunk with many segments, each bearing uniramous legs (FIG. 31-27).

Centipedes (“hundred-legged”) have one pair of legs on each segment behind the head. Most centipedes do not have

Table 31-5 Major Arthropod Clades

Clade and Selected Groups	Body Divisions	Appendages: Antennae, Mouthparts	Appendages: Legs	Gas Exchange	Development	Main Habitat
MYRIAPODS Chilopods (centipedes) Diplopods (millipedes)	Head with segmented body	Uniramous Antennae: one pair Mouthparts: mandibles, maxillae	Chilopods: one pair/segment Diplopods: usually two pairs/segment	Tracheae	Direct	Terrestrial
CHELICERATES Merostomes Horseshoe crabs Arachnids Spiders, scorpions, ticks, mites	Cephalothorax and abdomen	Uniramous Antennae: none Mouthparts: chelicerae, pedipalps	Merostomes: four pairs of walking legs Arachnids: four pairs on cephalothorax	Merostomes: gills Arachnids: book lungs or tracheae	Direct, except mites and ticks	Merostomes: marine Arachnids: mainly terrestrial
PANCRUSTACEANS Crustaceans Lobsters, crabs, shrimp, isopods (Malacostraca) Barnacles (Cirripedia) Copepods (Copepoda)	Head, thorax, and segmented abdomen	Biramous Antennae: two pairs Mouthparts: mandibles, two pairs of maxillae (for handling food)	Typically one pair/segment	Gills	Usually larval stages (nauplius larva)	Marine or freshwater; a few are terrestrial
Hexapods (insects) Bees, ants, grasshoppers, roaches, flies, beetles	Head, thorax, and abdomen (some multi-segmented)	Uniramous Antennae: one pair Mouthparts: mandibles, maxillae	Three pairs on thorax	Tracheae; gills in aquatic species	Typically, larval stages; most with complete metamorphosis	Mainly terrestrial

Figure 31-26 Fossil trilobites

These extinct arthropods (*Phacops rana*) were about 3 cm (1.2 in.) long. Note the large, well-developed eyes visible on either side of the head region. Biologists consider these extinct marine arthropods among the most primitive members of the arthropods. Trilobites flourished in the ocean during the Paleozoic era.

enough legs to merit their name; typically, they have approximately 30, although a few species have 100 or more. Because centipedes have long legs, they are able to run rapidly. They are predators that feed on other animals, mostly insects. Larger centipedes eat snakes, mice, and frogs. Using their poison claws located just behind the head on the first trunk segment, centipedes capture and kill their prey.

Millipedes (“thousand-legged”) have two pairs of legs on most body segments. They are not as agile as chilopods, and most species can crawl only slowly over the ground. However, they can powerfully force their way through earth and rotting wood. Millipedes are generally herbivorous and feed on both living and dead vegetation.

Chelicerates are the only arthropods without antennae Chelicerates are a monophyletic group that includes the merostomes (horseshoe crabs) and the arachnids. Chelicerates are now considered the sister group to all of the other arthropods. The chelicerate body consists of a *cephalothorax* (fused head and thorax) and an abdomen. Chelicerates have no chewing mandibles. Instead, the first appendages, located immediately anterior to the mouth, are a pair of **chelicerae** (sing., *chelicera*), fanglike feeding appendages. Most chelicerates suck fluid food from their prey. The second appendages are the *pedipalps*. The chelicerae and pedipalps are modified to perform different functions in various groups, including manipulation of food, locomotion, defense, and copulation. The four pairs of legs on the cephalothorax are specialized for walking.

Almost all the *merostomes* are extinct. Only the horseshoe crabs have survived, essentially unchanged for more than 350 million years. *Limulus polyphemus*, the species common along the Atlantic shore of North America, is horseshoe-shaped (FIG. 31-28a). Its long, spikelike tail is used in locomotion, not for defense or offense. Horseshoe crabs feed at night, capturing mollusks, worms, and other invertebrates that they find on the sandy ocean floor.

(a) Centipede (*Lithobius*). Centipedes have one pair of uniramous appendages per segment.

(b) Millipede (*Diplopoda pachydesmus*). Note the two pairs of uniramous appendages per segment.

Figure 31-27 Myriapods

Arachnids include spiders, scorpions, ticks, harvestmen (daddy longlegs), and mites (FIGS. 31-28b and c). Most of the approximately 80,000 named species are predators that feed on insects and other small arthropods. Most arachnids have six pairs of jointed appendages. In spiders the first appendages, the chelicerae, are used to penetrate prey; some species use the chelicerae to inject venom into their prey. Spiders use the second pair of appendages, the pedipalps, to manipulate food.

Many arachnid species have pedipalps modified as sense organs for tasting food or for reproduction (for sperm transfer and courtship displays). Scorpions use their very large pedipalps as pincers for capturing prey. Chelicerates use the remaining four pairs of appendages for walking.

Typically, spiders have eight eyes arranged in two rows of four each along the anterior dorsal edge of the cephalothorax. The eyes detect movement, locate objects, and in some species form a relatively sharp image.

Gas exchange in arachnids takes place by tracheal tubes, book lungs, or both. A *book lung* consists of 15 to 20 parallel plates (like pages of a book) that contain tiny blood vessels. Air enters the body through abdominal slits and circulates between the plates. As air passes over the blood vessels in the plates, oxygen diffuses into the blood and carbon dioxide diffuses out of the blood into the air. As many as four pairs of book lungs provide an extensive surface area for gas exchange.

Spiders have unique glands in the abdomen that secrete silk, an elastic protein that is spun into fibers by organs called *spinnerets*. The silk is liquid as it emerges from the spinnerets but hardens after it leaves the body. Spiders use silk to build nests, to encase their eggs in a cocoon, and in some species to trap prey in a web. Many spiders lay down a silken dragline that serves both as a safety line and a means of communication between members of a species. From the type of dragline, another spider can determine the sex and maturity level of the spinner.

Although all spiders (and scorpions) have poison glands useful in capturing prey, only a few produce poison toxic to humans. The most widely distributed venomous spider in the United States is the black widow (see Fig. 31-28b). Its venom is a neurotoxin that interferes with transmission of messages from nerves to muscles. The shiny black female is about 3.8 cm (1.5 in.) long with a red or orange hourglass-shaped marking on the underside of its abdomen. Adult male black widow spiders are smaller and are harmless. After mating, the female sometimes kills and eats the male.

The brown recluse spider (*Loxosceles reclusa*) is more slender than the black widow and has a violin-shaped stripe on its dorsal cephalothorax. Its venom destroys the tissues surrounding the bite. Although painful, spider bites cause fewer than three fatalities per year in the United States.

Mites are incredibly abundant, but are rarely noticed because of their small size. Some mites contribute to soil fertility by breaking down organic matter. However, many mites are serious nuisances. They eat crops and are external parasites that infest livestock and pets. Some species have modified body shapes and reduced appendages, adaptations for their parasitic lifestyles. Chiggers (red bugs), the larval form of some red mite species, attach themselves to the skin and secrete an irritating

(a) Horseshoe crabs (*Limulus polyphemus*). The only living merostomes are a few closely related species of horseshoe crabs. Seasonally, horseshoe crabs return to beaches for mating.

(b) A female black widow spider (*Latrodectus mactans*) rests on her web. The venom of the black widow spider is a neurotoxin.

(c) The house dust mite *Dermatophagoides*. This mite, a common inhabitant of homes, is associated with house dust allergies (color-enhanced SEM).

Figure 31-28 Chelicerates

digestive fluid that may cause itchy red welts. Certain mites cause mange in dogs and other domestic animals.

Larger than mites, ticks are parasites on dogs, deer, and many other animals. They transmit the bacteria that cause diseases such as Rocky Mountain spotted fever and Lyme disease (see Fig. 54-2).

Clade Pancrustacea includes the crustaceans and insects Researchers have provided a variety of molecular evidence, including genome analyses, to support this clade. Morphological data, including eye structure, also supports Pancrustacea. Many systematists now think that insects (hexapods) evolved from early crustaceans and refer to insects as “terrestrial crustaceans.”

Crustaceans are vital members of marine food webs Crustaceans include lobsters, crabs, shrimp, and barnacles plus tens of thousands of smaller species with great diversity (FIG. 31-29). Many crustaceans are primary consumers of algae and detritus. Countless billions of microscopic crustaceans are part of marine zooplankton, the free-floating, mainly microscopic organisms in the upper layers of the oceans. These crustaceans are food for many fishes and other marine animals, such as certain baleen whales. Paleobiologists have dated crustacean fossils to the Cambrian period (more than 505 mya).

A distinctive feature of many crustaceans is the *nauplius larva*, which is often the first stage after hatching. This larva has only the most anterior three pairs of appendages. Crustaceans are also characterized by mandibles, biramous appendages, and two pairs of **antennae**. Their antennae, which are the first and second pairs of appendages, serve as sensory organs for touch and taste. Most adult crustaceans have compound eyes, and many crustaceans have **statocysts**, sense organs that detect gravity (see Fig. 43-6).

The hard **mandibles**, used for biting and grinding food, are the third pair of appendages; they lie on each side of the ventral mouth. Crustaceans show great diversity in the number of appendages posterior to the mandibles. Some species have several pairs of appendages near the mouth, called **maxillae** and maxillipeds, that manipulate and hold food. More posteriorly along the thorax and along the segmented abdomen, other appendages are modified for swimming, walking, defense, sensation, mating, or carrying eggs or young.

Crustaceans are primarily aquatic; not surprisingly, they typically have gills for gas exchange. Two large glands located in the head excrete metabolic wastes and regulate salt balance. Most crustaceans have separate sexes. During copulation, the male uses specialized appendages to transfer sperm into the female. Many crustaceans hatch into a nauplius larva and then molt through a series of larval stages before developing the adult body form. However, some species resemble small adults immediately upon hatching. Newly hatched animals may resemble adults, or they may undergo successive molts as they pass through a series of larval stages before developing an adult body.

Barnacles, the only sessile crustaceans, differ markedly in external anatomy from other members of their clade. They are marine suspension feeders that secrete limestone cups within

Colin Milkins/Getty Images

Wolfgang Polzer/Alamy Stock Photo

(b) Sponge crab (*Criptodromia octodenta*) wearing a sponge on its back. The sponge provides camouflage and shelter. The sponge crab uses its claws to cut out a fragment from a sponge and then trims the sponge to conform to its own shape. The last two pairs of the crab's legs bend upward over the crab's body and hold the sponge in place. The sponge grows along with the crab.

Figure 31-29 Crustaceans

which they live (see Fig. 31-29a). The larvae of barnacles are free-swimming forms that go through several molts. They eventually become sessile and develop into the adult form. Louis Agassiz, a 19th-century naturalist, described the barnacle as “nothing more than a little shrimplike animal standing on its head in a limestone house and kicking food into its mouth.”

The bane of marine boaters, barnacles can proliferate on ship bottoms in great numbers. Barnacles can reduce the speed

of a ship by up to 10% and increase fuel consumption by as much as 40%. The U.S. Office of Naval Research has been testing an underwater grooming robot (the HULL BUG) that cleans barnacles, oysters, and other marine life from the hulls of ships when they are in port. They project that HULL BUGS will save about \$500 million annually in extra fuel costs and maintenance.

Isopods are mainly tiny (5 to 15 mm in length) marine crustaceans that inhabit the ocean floor. However, this group also includes some terrestrial animals: pill bugs and sow bugs. The most abundant crustaceans are the *copepods*, which are typically microscopic. Marine copepods are the most numerous component of zooplankton.

The largest and most familiar order of crustaceans, Decapoda, contains more than 10,000 species of lobsters, crayfish, crabs, and shrimp. Most **decapods** are marine, but a few, such as crayfish, certain shrimp, and a few crabs, live in fresh water. The crustaceans in general and the decapods in particular show striking specialization and differentiation of parts in the various regions of the animal. For example, the appendages in the different parts of the body differ markedly in form and function (FIG. 31-30).

In the lobster the five segments of the head and the eight segments of its thorax are fused into a cephalothorax, which is covered on the top and sides by a shield, the *carapace*, composed of chitin impregnated with calcium salts. The two pairs of antennae serve as chemoreceptors and tactile sense organs. The mandibles are short and heavy, with opposing surfaces used in grinding and biting food. Behind the mandibles are two pairs of accessory feeding appendages: the first and second maxillae.

The appendages of the first three segments of the thorax are the maxillipeds, which aid in chopping up food and passing it to the mouth. The fourth segment of the thorax has a pair of large *chelipeds*, or pinching claws. The last four thoracic segments bear walking legs. Gills for respiration branch dorsally from each of the thoracic appendages.

The appendages of the first abdominal segment are part of the reproductive system and are used by the male to transfer sperm. The following four abdominal segments bear paired *swimmerets*, small paddlelike structures used by some decapods for swimming and by the females of all species for holding eggs. Each branch of the sixth abdominal appendages consists of a large flattened structure. Together with the flattened posterior end of the abdomen, they form a tail fan used for swimming backward.

Insects are articulated, tracheated hexapods With more than one million described species (and perhaps millions more not yet identified), insects are the most successful group of animals on our planet in terms of number of individuals, number of species, diversity, and geographic distribution (TABLE 31-6). What they lack in size, insects make up in sheer numbers. If we could weigh all the insects in the world, their weight would exceed that of all the remaining terrestrial animals. Although primarily terrestrial, some insect species live in fresh water, a few are truly marine, and others inhabit the shore between the tides.

The earliest fossil insects—primitive, wingless species—date to the Devonian period more than 360 mya. Insect fossils from the Carboniferous period more than 310 mya include both wingless and primitive winged species. Cockroaches, mayflies, and cicadas

Figure 31-30 Anatomy of the lobster

(a) Like other decapods, the spiny lobster (*Panulirus argus*) has five pairs of walking legs. The first pair of walking legs is modified as chelipeds (*large claws*). Photographed in Grand Cayman. (b) Ventral view of a lobster. Note the variety of specialized appendages.

are among the insects that have survived relatively unchanged from the Carboniferous period to the present day. Hexapods form a very large monophyletic group, the clade **Hexapoda**. We describe insects as *articulated* (jointed), *tracheated* (having tracheal tubes for gas exchange) *hexapods* (having six feet).

The insect body consists of three distinct parts: head, thorax, and abdomen (FIG. 31-31). An insect's uniramous (unbranched) appendages include three pairs of legs that extend from the adult thorax and, in many orders, one or two pairs of wings. One pair of antennae protrudes from the head, and the sense organs include both simple and compound eyes. The complex mouthparts, which include mandibles and maxillae, are adapted for piercing, chewing, sucking, or lapping.

Table 31-6 Some Orders of Insects

Order, Number of Species, Some Characteristics	Representative Adult	Order, Number of Species, Some Characteristics	Representative Adult
HOMOPTERA (43,000)* Leafhoppers, scale insects Typically, two pairs of membranous wings; piercing-sucking mouthparts form beak; parasites of plants; vectors of plant diseases; incomplete metamorphosis	 Buffalo treehopper <i>Stictocephala bubalus</i>	LEPIDOPTERA (160,000) Moths, butterflies Usually two pairs of membranous, colorful, scaled wings; larvae are wormlike caterpillars with chewing mouthparts for eating plants; adult mouthparts adapted for sucking nectar; complete metamorphosis	 Luna moth <i>Aetias luna</i>
ODONATA (6000) Dragonflies, damselflies Two pairs of long membranous wings; chewing mouthparts; large, compound eyes; active predators; larvae very different from adult; incomplete metamorphosis	 Damselfly <i>Ischnura elegans</i>	DIPTERA (151,000) Houseflies, mosquitoes, fruit flies Only forewings functional in flying; hindwings reduced to small, knob-like balancing organs (halteres); mouthparts usually adapted for sucking (and piercing in some); larvae are maggots that damage domestic animals or food; adults transmit diseases such as sleeping sickness, yellow fever, and malaria; complete metamorphosis	 Deerfly <i>Chrysops vittatus</i>
ORTHOPTERA (27,000) Grasshoppers, crickets Forewings leathery, hindwings membranous; chewing mouthparts; most herbivorous, some cause crop damage; some predatory; incomplete metamorphosis	 Fork-tailed bush katydid <i>Scudderella furcata</i>	SIPHONAPTERA (2000) Fleas No wings; piercing-sucking mouthparts; legs adapted for clinging and jumping; parasites on birds and mammals; vectors of bubonic plague and typhus; complete metamorphosis	 Dog flea <i>Ctenocephalides canis</i>
BLATTODEA (4000) Cockroaches When wings present, forewings leathery, hindwings membranous; chewing mouthparts; legs adapted for running; incomplete metamorphosis	 American cockroach <i>Periplaneta americana</i>	COLEOPTERA (360,000) Beetles, weevil Forewings modified as protective coverings for membranous hindwings (which are sometimes absent); chewing mouthparts; largest order of insects; most herbivorous; some aquatic; many larvae are grubs; complete metamorphosis	 Colorado potato beetle <i>Leptinotarsa decemlineata</i>
ISOPTERA (2500) Termites Two pairs of wings, or none; wings shed by sexual forms after mating; chewing mouthparts; social insects, form large colonies; eat wood; incomplete metamorphosis	 Eastern subterranean termite <i>Reticulitermes flavipes</i>	HYMENOPTERA (more than 125,000) Ants, bees, wasps Usually two pairs of membranous wings; mouthparts may be modified for sucking or lapping nectar; many are social insects; some sting; important pollinators; complete metamorphosis	 Bald-faced hornet <i>Vespula maculata</i>
PHTHIRAPTERA (3000) Lice, sucking lice No wings; piercing-sucking mouthparts; ectoparasites of mammals; head and body louse and crab louse are human parasites; vectors of typhus fever; incomplete metamorphosis	 Human head and body louse <i>Pediculus humanus</i>	ZYGENTOMA (600) Silverfish No wings; biting-chewing mouthparts; two to three "tails" extend from posterior tip of abdomen; inhabit dead leaves; eat starch in books; direct development	 Silverfish <i>Lepisma saccharina</i>
HEMIPTERA (85,000) Chinch bugs, bedbugs, water striders; cicadas and aphids Hindwings membranous; forewings smaller; piercing-sucking mouthparts form beak; most herbivorous; some parasitic; incomplete metamorphosis	 Chinch bug <i>Blissus leucopterus</i>		

* The number of species listed for each order is approximate. Estimates vary widely.

(a) **External structure.** Note the three pairs of segmented legs.

(b) **Internal anatomy.**

Figure 31-31 Anatomy of the grasshopper

Insects, the most successful of all animals, are articulated, tracheated hexapods.

The unique **tracheal system** of insects has made an important contribution to their diversity. Air enters the **tracheal tubes**, or tracheae, through **spiracles**, tiny openings in the body wall. Oxygen passes directly to the internal organs via the tubes branching throughout the body. This effective oxygen delivery system permits insects to have the high metabolic rate necessary for activities such as flight, even though they have an open circulatory system.

Insects excrete metabolic wastes through two or more **Malpighian tubules**. These tubules receive metabolic wastes from the blood, concentrate the wastes, and discharge them into the intestine. Unique to terrestrial arthropods, Malpighian tubules also perform the extremely important function of conserving water (see Fig. 48-4).

The sexes are separate, and fertilization takes place internally. Several molts occur during development. The immature stages between molts are called *instars*. Primitive insects with no wings, such as silverfish, have direct, or simple, development: the young hatch as juveniles that resemble the adult form. Other insects, such as grasshoppers and cockroaches, undergo **incomplete metamorphosis** in which the egg gives rise to a larva that resembles the adult in many ways but lacks functional wings and reproductive structures. The larva goes through a series of molts during which it becomes more and more like the adult.

Most insects, including bees, butterflies, and fleas, undergo **complete metamorphosis** with four distinct stages in the life cycle: *egg*, *larva*, *pupa*, and *adult* (FIG. 31-32). The wormlike larva does not look at all like the adult. For example, caterpillars have a body form entirely different from that of butterflies. Typically, an insect spends most of its life as a larva, which has chewing mouthparts. Eventually, the larva stops feeding, molts, and enters a pupal stage, usually within a protective cocoon or underground burrow. The **pupa** does not feed and typically

cannot defend itself. Energy reserves stored during the larval stage are spent remodeling its body. When it emerges as an adult, it is equipped with functional wings and reproductive organs.

Certain species of bees, ants, and termites live as colonies or societies made up of several different types of individuals, each adapted for some particular function. Insects communicate by tactile, auditory, visual, or chemical signals. The members of some insect societies communicate with one another by “dances.” Insects also communicate by means of **pheromones**, hormonelike molecules secreted to the external environment that influence the behavior (or development) of members of the same species. For example, certain ant species use pheromones to mark trails and to warn of danger. Many insects use pheromones to attract mates. Social insects and their communication are discussed in Chapter 52.

Adaptations that contribute to the biological success of insects What are the secrets of insect success? The tough exoskeleton protects insects from predators and helps reduce water loss. Segmentation allows mobility and flexibility and permits regional specialization of the body. For example, cephalization and highly developed sense organs are important in both offense and defense.

The insect body plan has been modified and specialized in so many ways that insects are adapted to a remarkable number of lifestyles. The jointed appendages are specialized for various types of feeding, sensory functions, and different types of locomotion (walking, jumping, swimming). For example, grasshopper mouthparts are adapted for biting and chewing leaves. Moth and butterfly mouthparts are adapted for sucking nectar from flowers, and mosquito mouthparts are adapted for sucking blood. Aphids and leafhoppers have mouthparts specialized to pierce plants and feed on plant juices.

Another adaptation that contributes to insect success is the ability to fly. Unlike other terrestrial invertebrates, which creep slowly along on or under the ground, many insects fly rapidly through the air. Their wings and small size facilitate their wide distribution and, in many instances, their immediate survival. For example, when a pond dries up, adult aquatic insects can fly to another habitat.

The reproductive capacity of insects is remarkable. Under ideal conditions, the fruit fly *Drosophila* can produce 25 generations in a single year! Insect eggs are protected by a thick membrane. In addition, several eggs may be enclosed in a protective egg case. By dividing the insect life cycle into different stages, complete metamorphosis reduces competition among members of the same species (intraspecific competition). For example, larval forms have different lifestyles, so they do not compete with adults for food or habitats.

Insects have many interesting adaptations for offense and defense (see Fig. 7-8). We all are familiar with the stingers of bees and wasps, which are specialized egg-laying structures (ovipositors). Many insects have **cryptic coloration**, which makes them appear as dead twigs or leaves. They blend into the background of their habitat, avoiding predators. Others mimic poisonous insects, deriving protection from this resemblance. Still others “play dead” by remaining motionless.

Key Point

Complete metamorphosis reduces competition among insects within the same species; larval forms do not compete with adults for food or habitats.

Figure 31-32 Complete metamorphosis in a Polyphemus moth

Insects, the most successful of all animals, are articulated, tracheated hexapods. This moth (*Antheraea polyphemus*) belongs to the family of giant silk moths.

CONNECT Which of the following stages is haploid? diploid? (1) embryo developing in egg, (2) larva, (3) pupa, (4) adult

Impact of insects on humans Not all insects compete with humans for food or cause us to scratch, swell up, or recoil from their presence. Bees, wasps, beetles, and many other insects pollinate the flowers of crops and fruit trees. Some insects destroy other insects that are harmful to humans. For example, dragonflies eat mosquitoes. And many organic farmers and home gardeners buy ladybird beetles, which are adept at ridding plants of aphids and other insect pests. Insects are important members of many food webs. Many species of birds, mammals, amphibians, reptiles, and fishes depend on insects for food. Some beetles and the larvae (maggots) of flies are detritus feeders: they break down dead plants and animals and their wastes, permitting nutrients to be recycled.

Various insect products are useful to humans. Bees produce honey as well as beeswax, which we use to make candles, lubricants, and other products. Shellac is made from lac, a substance given off by certain scale insects that feed on the sap of trees. And the labor of silkworms provides us with beautiful fabric.

On the negative side, each year insects destroy crops worth billions of dollars. Fire ants not only inflict painful stings but cause farmers serious economic loss because of their large mounds, which damage mowers and other farm equipment. Moths damage clothing, and termites destroy

buildings. Blood-sucking flies, screwworms, lice, fleas, and other insects annoy and transmit disease to humans and domestic animals. Mosquitoes are vectors of yellow fever and malaria (see Fig. 26-7). Fleas and lice transmit the rickettsia that cause typhus, and houseflies sometimes transmit typhoid fever and dysentery. Tsetse flies transmit African sleeping sickness, and fleas may be vectors of bubonic plague.

In this chapter we have surveyed the major groups of protostomes. **TABLE 31-7** summarizes these groups. Chapter 32 focuses on the deuterostomes, which include the echinoderms and chordates.

CHECKPOINT 31.3

- **CONNECT** What characteristics distinguish nematodes from flatworms?
- **CONNECT** Describe four key arthropod characteristics, and explain how each contributes to arthropod success.
- How do crustaceans differ from chelicerates?
- **CONNECT** Describe four adaptations that have contributed to insect success.

Table 31-7 Overview of Sponges, Cnidarians, Ctenophores, and Protostomes

Major Groups		Body Plan	Some Key Characteristics
Poriferans (sponges)		Asymmetrical; cells loosely arranged and do not form true tissues; body is sac with pores, central cavity, and osculum	Collar cells (choanocytes); aquatic, mainly marine
Cnidarians Medusozoans Hydras, jellyfish Anthozoans Sea anemones, corals		Radial symmetry; diploblastic; gastrovascular cavity with one opening	Tentacles with cnidocytes (stinging cells) that discharge nematocysts; two body forms: polyp and medusa; some form colonies; mainly marine
Ctenophores (comb jellies)		Biradial symmetry; diploblastic; digestive system with mouth and anal pores	Eight rows of cilia that resemble combs; tentacles with adhesive glue cells; marine predators
PROTOSTOMES: LOPHOTROCHOZOAN CLADE			
Flatworms Free-living Planarians Parasitic Flukes, tapeworms		Bilateral symmetry; triploblastic; simple organ systems; gastrovascular cavity with one opening	No body cavity; some cephalization; some are free-living predators; many are parasites
Nemerteans (ribbon worms)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube*	Proboscis (long, muscular tube that can be everted to capture prey); true coelom reduced; mainly marine predators
Mollusks Chitons Gastropods Snails, slugs Bivalves Clams, oysters Cephalopods Squids, octopuses		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Soft body typically covered by dorsal shell; flat, muscular foot; mantle covers visceral mass; most have a radula (belt of teeth); most are marine
Annelids Errantians Marine worms Sedentarians Earthworms, leeches		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Segmented body; most have setae, bristles that provide traction during crawling
Lophophorates Brachiopods, phoronids, bryozoans		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Lophophore (ring of ciliated tentacles) surrounds mouth, captures suspended particles in water; mainly sessile, marine animals
Rotifers (wheel animals)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; pseudocoelom	Crown of cilia at anterior end; cell number constant; microscopic, aquatic animals
PROTOSTOMES: ECDYSOZOAN CLADE			
Nematodes (roundworms) <i>Ascaris</i> , hookworms, trichina worms		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; pseudocoelom	Cylindrical, threadlike body; widely distributed in soil and aquatic sediments; important as decomposers; many are predators; some are parasites
Arthropods Myriapods Centipedes, millipedes Chelicerates Horseshoe crabs, spiders Pancrustaceans Crustaceans, hexapods (insects)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube; true coelom	Segmented body; exoskeleton; paired, jointed appendages; insects and many crustaceans have compound eyes; insects have tracheal tubes for gas exchange; wings

* A complete digestive tube has a mouth for food intake and an opening (anus) for elimination of wastes.

Summary: Focus on Learning Objectives

31.1 Sponges, Cnidarians, and Ctenophores (page 642)

1 Identify important characteristics of poriferans.

- The **poriferans**, or sponges, are characterized by flagellate **collar cells (choanocytes)**, which generate a water current that brings food and oxygen to the cells. Collar cells also trap and phagocytize food particles. The sponge body is a sac with tiny openings through which water enters; a central cavity, or **spongocoel**; and an open end, or **osculum**, through which water exits. The cells of sponges are loosely associated; they do not form true tissues.

2 Identify distinguishing characteristics of cnidarians, describe their two main clades, and list animals that belong to each clade.

- Cnidarians** are characterized by radial symmetry, two tissue layers, and **cnidocytes**, cells containing stinging organelles called **nematocysts**. The **gastrovascular cavity** has a single opening that serves as both mouth and anus. Nerve cells form irregular, nondirectional **nerve nets** that connect sensory cells with contractile and gland cells.
- The life cycle of many cnidarians includes a sessile **polyp** stage (a form with a dorsal mouth surrounded by tentacles) and a free-swimming **medusa** (jellyfish) stage.
- The cnidarians form two major clades: medusozoans and anthozoans. Medusozoans include *hydrozoans* (hydras and jellyfish). Jellyfish are generally medusae. *Anthozoans* (sea anemones and corals) are polyps and may be solitary or colonial; anthozoans differ from hydrozoans in the organization of the gastrovascular cavity.

3 Identify characteristics of ctenophores.

- Ctenophores**, or *comb jellies*, are fragile, luminescent marine predators with biradial symmetry. Ctenophores have eight rows of cilia that resemble combs. They are diploblastic and have tentacles with adhesive glue cells.

31.2 The Lophotrochozoa (page 649)

4 Summarize what is known about the phylogeny of the lophotrochozoans and cite the adaptive advantages of having a coelom and of cephalization.

- The **Lophotrochozoa** make up a clade that includes flatworms, nemerteans, mollusks, annelids, the lophophorate phyla, and rotifers.

- The true **coelom** is a fluid-filled body cavity completely lined by mesoderm that lies between the digestive tube and the outer body wall. The coelom brings about the *tube-within-a-tube body plan*. The body wall is the outer tube. The inner tube is the digestive tube. The coelom can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid. The coelom is a space in which internal organs, including gonads, can develop; it helps transport materials and protects internal organs.
- Cephalization**, the evolution of a head with the concentration of sense organs and nerve cells at the anterior end, increases the effectiveness of a bilateral animal to actively find food, shelter, and mates and to detect enemies.

5 Identify distinguishing characteristics of flatworms and nemerteans, and describe the main groups of flatworms, giving examples of animals that belong to each.

- The *flatworms* are **acoelomate** (have no coelom) animals with bilateral symmetry, cephalization, three definite tissue layers, and well-developed organs. Many flatworms are **hermaphrodites**: a single animal produces both sperm and eggs. Flatworms have a ladder-type nervous system, typically consisting of sense organs and a simple brain composed of two **ganglia**. The ganglia are connected to two nerve cords that extend the length of the body. **Protonephridia** function in osmoregulation and disposal of metabolic wastes.
- Two main flatworm clades are recognized: A free-living clade, the turbellarians, includes planarians. The parasitic clade includes the trematodes and monogeneans (*flukes*) and cestodes, the tapeworms.
- The parasitic flukes and tapeworms typically have suckers or hooks for holding on to their hosts; they have complicated life cycles with intermediate hosts and produce large numbers of eggs.
- Nemerteans** (ribbon worms) are characterized by the *proboscis*, a muscular tube used in capturing food and in defense. Nemerteans have a complete digestive tract with mouth and anus, and a circulatory system. The coelom is reduced.

6 Describe the main characteristics of mollusks and of the four clades of mollusks discussed, giving examples of each group.

- Mollusks** are soft-bodied animals typically covered by a shell. They have a ventral *foot* for locomotion and a pair of folds called the **mantle** that covers the **visceral mass**, a concentration of body organs.

- Mollusks have an **open circulatory system**, except for cephalopods, which have a **closed circulatory system**. A rasplike **radula** functions as a scraper in feeding in all groups except the bivalves, which are filter feeders. Typically, marine mollusks have free-swimming, ciliated **trochophore larvae**.
- Four mollusk clades are chitons, gastropods, bivalves, and cephalopods. **Chitons** have a dorsal shell consisting of eight overlapping dorsal plates. **Gastropods** include the snails, slugs, and their relatives. They have a well-developed head with tentacles and eyes. The body undergoes **torsion**, a twisting of the visceral mass.
- **Bivalves** are aquatic clams, scallops, and oysters. A two-part shell, hinged dorsally, encloses the bodies of these filter feeders. **Cephalopods** include the squids, octopuses, and *Nautilus*. These active, predatory swimmers have tentacles surrounding the mouth, which is located in the large head.

7 Describe the principal characteristics of annelids and of the two clades of annelids discussed, giving examples of each group.

- The **annelids**, the segmented worms, include many aquatic worms, earthworms, and leeches. Annelids have long bodies with **segmentation** both internally and externally; their large, compartmentalized coelom serves as a hydrostatic skeleton.
- **Errantians** and **sedentarians** make up the two annelid clades. Sandworms and tubeworms make up the errantian clade. These *polychaetes* are marine annelids characterized by **parapodia**, appendages used for locomotion and gas exchange. The parapodia bear many bristlelike structures called **setae**. Polychaetes also differ from other annelids in having a well-defined head with sense organs.
- Earthworms and leeches are sedentarians. *Oligochaetes*, the group that includes the earthworms, are characterized by a few short setae per segment. The body is divided into more than one hundred segments separated internally by **septa**. Earthworms are hermaphroditic.
- Leeches do not have setae or appendages. Parasitic leeches are equipped with suckers for holding on to their host.

8 Describe the distinguishing characteristics of the lophophorates and of the rotifers.

- The **lophophorates**, marine animals that have a lophophore, include the *brachiopods*, *phoronids*, and *bryozoans*. The **lophophore**, a ciliated ring of tentacles surrounding the mouth, is specialized for capturing suspended particles in the water.
- **Rotifers** are pseudocoelomates that are thought to have evolved from animals with a true coelom. They have a crown of cilia at their anterior end.

31.3 The Ecdysozoa (page 662)

9 Summarize what is known about the phylogeny of the ecdysozoans.

- **Ecdysozoa** is one of the three major animal clades; its validity is based on many types of evidence, including molecular data. Members of this group go through the process of **ecdysis**, or **molting**, during which an animal sheds its outer covering; the covering is replaced by the growth of a new one.

10 Describe characteristics of nematodes and identify four parasitic nematodes.

- **Nematodes**, or *roundworms*, have a pseudocoelom. The body is covered by a tough **cuticle** that helps prevent desiccation. Parasitic nematodes that infect humans include *Ascaris*, *hookworms*, *trichina worms*, and *pinworms*.

11 Describe six key characteristics of arthropods, summarize proposed phylogeny of arthropods, and distinguish among arthropod clades; give examples of animals that belong to each group.

- **Arthropods** are segmented protostomes with *paired, jointed appendages* and an armorlike **exoskeleton** of chitin. Molting is necessary for the arthropod to grow. Arthropods have an open circulatory system with a dorsal heart that pumps **hemolymph**. Aquatic forms have gills for gas exchange; terrestrial forms have either **tracheae** or *book lungs*.
- Based on molecular and other data, arthropods are currently assigned to three clades: **myriapods**, **chelicerates**, and **pancrustaceans**.
- The *trilobites* are extinct marine arthropods covered by a hard, segmented shell. Each segment had a pair of **biramous appendages**, appendages with two jointed branches: an inner walking leg and an outer gill branch.
- The myriapods include centipedes and millipedes. Members of this clade have **uniramous appendages**, that is unbranched appendages, and a single pair of antennae.
- The *merostomes* (horseshoe crabs) and the **arachnids** (spiders, mites, and their relatives) are chelicerates. The chelicerate body consists of a cephalothorax and abdomen; there are six pairs of uniramous, jointed appendages, of which four pairs serve as legs. The first appendages are **chelicerae**, and the second are *pedipalps*. These appendages are adapted for manipulation of food, locomotion, defense, or copulation. Chelicerates have no antennae and no mandibles.
- **Pancrustaceans** are a very large clade that includes crustaceans and insects (hexapods). Lobsters, crabs, shrimp, pill bugs, and barnacles, and their many relatives are familiar crustaceans. The crustacean body typically consists of a cephalothorax and abdomen. Crustaceans vary greatly in the appearance and in the number of biramous appendages. Crustaceans have two pairs of **antennae** that sense taste and touch, and a pair of **mandibles** used for chewing. Two pairs of **maxillae**, posterior to the mandibles, manipulate and hold food. The decapod crustaceans typically have five pairs of walking legs.
- An insect is an *articulated, tracheated hexapod*; its body consists of head, thorax, and abdomen. Insects have uniramous appendages, a single pair of antennae, **tracheae** for gas exchange, and **Malpighian tubules** for excretion.

12 Identify adaptations that have contributed to the biological success of insects.

- The biological success of the insects can be attributed to their many adaptations, including a versatile exoskeleton, segmentation, specialized jointed appendages, highly

developed sense organs, and ability to fly. **Complete metamorphosis**, transition during the life cycle from one developmental stage to another, includes egg, larva, pupa, and adult stages. Complete metamorphosis reduces

competition within the same species. Effective reproductive strategies, effective mechanisms for defense and offense, and the ability to communicate have evolved in insects.

Test Your Understanding

Know and Comprehend

- Collar cells (choanocytes) are characteristic of (a) poriferans (b) cnidarians (c) most coelomates (d) lophotrochozoans (e) ecdysozoans
- Cnidocytes (a) are characteristic of sponges (b) are found among cells lining the gastrovascular cavity (c) contain stinging organelles (d) are lined with mesoderm (e) have two main shapes
- Which of the following is associated with the evolution of the coelom? (a) radial symmetry (b) tube-within-a-tube body plan (c) incomplete metamorphosis (d) bilateral symmetry (e) development of ganglia
- Trochophore larvae are characteristic of (a) arthropods (b) cnidarians (c) flatworms (d) mollusks (e) crustaceans
- Which of the following is *not* an adaptation to parasitic life? (a) production of a few well-protected eggs (b) hooks (c) suckers (d) reduced digestive system (e) intermediate host
- An open circulatory system (a) is characteristic of squids and other active mollusks (b) permits contracting muscles to recover quickly (c) has no blood vessels (d) is a unique characteristic of annelids (e) has hemolymph, which bathes tissues directly
- Which of the following characteristics is associated with mollusks? (a) mandibles (b) mantle (c) pedipalps (d) chelipeds (e) setae
- Trilobites (a) were early mollusks (b) are onychophorans (c) are characterized by parapodia and setae (d) were early arthropods (e) are an evolutionary link between annelids and arthropods
- Which of the following is *not* characteristic of arthropods? (a) exoskeleton (b) pseudocoelom (c) paired, jointed appendages (d) chitin (e) segmentation
- Which of the following is characteristic of insects? (a) biramous appendages (b) two pairs of antennae (c) chelicerae (d) eight legs (e) mandibles

Apply and Analyze

- The correct sequence of complete metamorphosis of an insect is (a) egg → immature form → adult (b) egg → trochophore larva → adult (c) egg → pupa → larva → adult (d) egg → larva → pupa → adult (e) adult → larva → egg → pupa
- VISUALIZE** Draw a cross section through a hydra. Label the epidermis, gastrodermis, gastrovascular cavity, and mesoglea.
- EVOLUTION LINK** Discuss important adaptations made possible by the development of the coelom.

- EVOLUTION LINK** Discuss the idea that every evolutionary adaptation has both advantages and disadvantages, using each of the following as an example: (a) cephalization, (b) the arthropod exoskeleton, and (c) segmentation with specialization.

Evaluate and Synthesize

- INTERPRET DATA** Imagine that you discover a new animal in a rain forest. It has an elongated, segmented body with bristles, and it has no obvious head. Where would you place this animal in the accompanying cladogram? Support your decision. Look at the more detailed cladogram in Figure 30-6a (in Chapter 30). What additional characteristics would help you place your animal in this cladogram? Explain your decision-making process.

- EVOLUTION LINK** Why have biologists stopped using type of body cavity as a major criterion for inferring relationships among animal groups?
- EVOLUTION LINK** Animal body plans have generally evolved from simple to more complex. How can we explain the exceptions?
- EVOLUTION LINK** Insects that undergo complete metamorphosis outnumber those that do not by more than 10 to 1. Hypothesize an explanation.
- SCIENCE, TECHNOLOGY, AND SOCIETY** Several international monitoring projects are gathering data to help us understand coral reef destruction. In your opinion, why is it important to take action to protect coral reefs? What role might technology play?

32 The Deuterostomes

KEY CONCEPTS

- 32.1** Echinoderms and chordates are the two most successful deuterostome lineages in terms of diversity, number of species, and number of individuals.
- 32.2** Echinoderms are characterized by radial symmetry in adults, a water vascular system, tube feet, and spiny skin.
- 32.3** At some time in its life, a chordate has a notochord; a dorsal, tubular nerve cord; a muscular postanal tail; and an endostyle (or thyroid gland).
- 32.4** Invertebrate chordates include tunicates and lancelets.
- 32.5** Shared derived characters of vertebrates include a vertebral column, a cranium, neural crest cells, and an endoskeleton of cartilage or bone.
- 32.6** Among the earliest vertebrates, ostracoderms were armored, jawless fishes. The extant hagfishes and lampreys have neither jaws nor paired fins.
- 32.7** Jaws and fins were key adaptations that contributed to the success of jawed fishes; the evolution of limbs was important in the transition to terrestrial life.
- 32.8** The evolution of the amniotic egg allowed animals to become fully terrestrial; the amniotic egg was the key adaptation leading to the evolution of reptiles and, later, to birds and mammals.

What does a sea star have in common with a fish, frog, hawk, or human? You may think it strange to group the echinoderms—the sea stars, sea urchins, and sand dollars—with the chordates, the clade (phylum) that includes humans and other animals with a vertebral column. However, even though these animals look and behave very differently from one another, fossil evidence and morphological, developmental, and molecular data suggest that chordates and echinoderms share a common ancestor and are closely related.

In Chapter 31 we discussed the two major protostome branches of the animal kingdom: the lophotrochozoans and the ecdysozoans. In this chapter we focus on the third major branch of the animal kingdom, the **deuterostomes**. Some biologists speculate that the last common ancestor of the deuterostomes was an animal that obtained food by filtering ocean water. The two major groups (phyla) of living animals assigned to the deuterostomes are the echinoderms (a group that includes sea stars and sea urchins) and the chordates. The largest chordate clade (subphylum) is Vertebrata, which includes the animals with which we are most familiar: fishes, amphibians, reptiles (including birds), and mammals. The Galápagos marine iguana is a reptile, a member of the vertebrate clade, that has many interesting adaptations (see photograph).

We begin this chapter with an introduction to the deuterostomes and a survey of the echinoderms. We then turn our attention to the chordates. We describe the key chordate characteristics

PHOTO: The Galápagos marine iguana (*Amblyrhynchus cristatus*), the only known marine lizard. This iguana lives on land and feeds along the shore and in the ocean. It is adapted to ingesting salt in its diet of red and green algae. It shoots out salty water through its nostrils. You can see encrusted salt as a white cap on its head. Charles Martin

and discuss the invertebrate chordates. After an introduction to the vertebrates, we discuss jawless fishes and the evolution of jaws, and later the origin of vertebrates with limbs. We discuss the evolution of the adaptations that made the transition to life on land possible. We then describe the evolution of amniotes, which encompasses reptiles (including birds) and mammals.

32.1 What Are Deuterostomes?

LEARNING OBJECTIVE

- 1 Identify shared derived characters of deuterostomes and briefly describe the hemichordates.

The deuterostomes (clade Deuterostomia) make up the third major branch of the animal kingdom. Deuterostomes include the *echinoderms*—the sea stars, sea urchins, and sand dollars—and the *chordates*, the phylum that includes humans and other *vertebrates* (animals with a vertebral column and bony cranium). Biologists also classify the **hemichordates**, a small group of wormlike marine animals, as deuterostomes. Hemichordates have a three-part body made up of a proboscis, collar, and trunk. These animals also have a characteristic ring of cilia surrounding the mouth. The most familiar of the hemichordates are the *acorn worms*, animals that live buried in mud or sand.

Deuterostomes evolved from a common ancestor during the Proterozoic eon more than 550 million years ago (mya). The major groups were present during the Early Cambrian period. Deuterostomes are characterized by several **shared derived characters** (synapomorphic characters), evolutionary novelties present in their most recent common ancestor (see Chapter 23). Evidence for the relatedness of the chordates, hemichordates, and echinoderms comes from molecular data and patterns of embryonic development. For example, deuterostomes are characterized by radial, rather than spiral, cleavage (see Chapter 30). Their cleavage is indeterminate, which means that the fate of their cells is fixed later in development than is the case in protostomes. In deuterostomes the mouth does not develop from the blastopore as in protostomes. The blastopore of deuterostomes becomes the anus (or is located near the future site of the anus), and the mouth develops from a second opening at the anterior end of the embryo, thus the name *deuterostome*, which is derived from the Greek words for “second mouth.”

At some time in their life cycle, most deuterostomes develop *pharyngeal slits*, openings that connect the pharynx with the outside environment. Although there is evidence that some early echinoderms had pharyngeal slits, the extant (living) echinoderms have lost this character. *Basal deuterostomes* (members of the earliest deuterostome group to evolve) have a type of larva with a loop-shaped band of cilia used for locomotion. Deuterostomes have a true coelom.

CHECKPOINT 32.1

- What are three shared derived characters of deuterostomes?

32.2 Echinoderms

LEARNING OBJECTIVE

- 2 Identify three shared derived characters of echinoderms and describe the main clades (classes) of echinoderms.

The **echinoderms** (clade [phylum] *Echinodermata*) have one of the most highly derived body plans in the animal kingdom. With their unusual symmetry, spiny skins, water vascular system, and tube feet, echinoderms are one of the most unique animal groups. Echinoderm larvae are bilaterally symmetrical, ciliated, and free-swimming. However, during development the body reorganizes, and the adult exhibits *pentaradial symmetry*, in which the body is arranged in five parts around a central axis. Biologists have hypothesized that early echinoderms were sessile and that radial symmetry evolved as an adaptation to that lifestyle. Their radial symmetry allows these animals to respond effectively in every direction of their surrounding environment.

The most unique derived character of echinoderms is the **water vascular system**, a network of fluid-filled canals and chambers. In the sea star, for example, sea water enters through small pores in the *madreporite*, a sievelike structure on the body surface. Cilia lining the canals of the system move the water along. Branches of the water vascular system lead to numerous tiny **tube feet** that extend when filled with fluid. Each tube foot receives fluid from the main system of canals. A rounded muscular sac, or **ampulla**, at the base of the foot stores fluid and is used to operate the tube foot. A valve separates each tube foot from other parts of the system. When the valve shuts, the ampulla contracts, forcing fluid into the tube foot. The fluid causes the tube foot to extend. At the bottom of the foot, a suction-type structure presses against and adheres to whatever surface the tube foot is on. The water vascular system functions in feeding and gas exchange, and it serves as a hydrostatic skeleton important in locomotion.

Another unique echinoderm character is the **endoskeleton**, an internal skeleton, covered by a thin, ciliated epidermis. The endoskeleton consists of calcium carbonate (CaCO_3) plates and spines. The name *Echinodermata*, derived from words meaning “spiny skinned,” was inspired by the spines that project outward from the endoskeleton. Some groups have pincer-like, modified spines called *pedicellariae* on the body surface. These structures, found only among the echinoderms, keep the surface of the animal free of debris.

Echinoderms have a well-developed coelom, containing coelomic fluid that transports materials. Although its structure varies in different groups, the complete digestive system is the most prominent body system. A variety of respiratory structures are found in the various clades. No excretory organs are present. Echinoderms have no brain. The nervous system is simple, generally consisting of a nerve ring with nerves that extend out from it. The sexes are usually separate, and eggs and sperm are generally released into the water, where fertilization takes place.

The fossil evidence suggests that echinoderms evolved from bilaterally symmetrical ancestors, probably during the Early Cambrian period. They achieved maximum diversity by the middle of the Paleozoic era, about 400 mya. By the beginning of

the Mesozoic era 252 mya, they had declined, leaving five main groups that have survived to the present day. Biologists have identified about 7000 living and more than 13,000 extinct species.

All echinoderms inhabit marine environments. They are found in the ocean at all depths. We consider the five extant clades: clade (class) Crinoidea, sea lilies and feather stars; clade (class) Asteroidea, sea stars; clade (class) Ophiuroidea, basket stars and brittle stars; clade (class) Echinoidea, sea urchins and sand dollars; and clade (class) Holothuroidea, sea cucumbers (TABLE 32-1 and FIG. 32-1).

Feather stars and sea lilies are suspension feeders

Feather stars and sea lilies (clade Crinoidea) are the oldest living echinoderms (see Fig. 32-1a). Although many extinct crinoids are known, relatively few living species have been identified. The feather stars are motile, although they often remain in the same location for long periods. Sea lilies are sessile and remain attached to the ocean floor by a stalk.

Crinoids are suspension feeders. The movement of the surrounding water brings food to them. Several branched, feathery arms extend upward. Numerous tube feet shaped like small tentacles are located along the feathery arms. These tube feet are coated with mucus that traps microscopic organisms. The oral surface (location of the mouth) is on the upper side of the disc. In all other echinoderms, the mouth is located on the underside of the disc, facing the ocean floor.

Many sea stars capture prey

Sea stars (commonly called starfish) are asteroids (clade Asteroidea; see Fig. 32-1b). Their bodies consist of a central disc from which

extend 5 to more than 20 arms, or rays (FIG. 32-2). The undersurface of each arm has hundreds of pairs of tube feet. The endoskeleton consists of a series of calcareous plates that permit some movement of the arms. Delicate dermal gills, small extensions of the body wall, carry on gas exchange. The mouth lies in the center of the underside of the disc.

Most sea stars are predators and scavengers that feed on cnidarians, crustaceans, mollusks, annelids, and even other echinoderms. A few species may catch small fish. The sea star’s water vascular system does not permit rapid movement, so its prey usually consists of stationary or slow-moving animals, such as clams.

To attack a clam or other bivalve mollusk, the sea star mounts it and assumes a humped position as it straddles the edge opposite the hinge. Then, holding itself in position with its tube feet, the sea star slides its thin, flexible stomach out through its mouth and between the closed, or slightly gaping, valves (shell parts) of the clam. While the clam is still in its own shell, the sea star secretes enzymes that digest the soft parts of the clam to the consistency of a thick soup. When the partly digested meal is taken into the sea star body, it is further digested by enzymes secreted by digestive glands located in each arm.

The circulatory system in sea stars is poorly developed and probably of little help in transporting materials. Instead, the coelomic fluid, which fills the large coelom and bathes the internal tissues, assumes this function. Metabolic wastes pass to the outside by diffusion across the tube feet and dermal gills. The nervous system consists of a ring of nervous tissue encircling the mouth and a nerve extending from this ring into each arm.

Sea daisies are a curious group of asteroids characterized by small, disc-shaped, flat bodies (less than 1 cm in diameter) with no arms or mouth. They inhabit bacteria-rich wood sunk in deep water and apparently absorb bacteria through their body surface.

Table 32-1 Echinoderms Clades		
Clade and Representative Animals		Characteristics
CRINOIDEA Feather stars, sea lilies		Feather stars motile; sea lilies, sessile, attach to ocean floor by stalk; oral surface on upper side of disc; tube feet along feathery arms trap microscopic organisms
ASTEROIDEA Sea stars		Arms (rays) extend from central disc; tube feet on undersurface of each arm; mouth in center of underside of disc; carnivorous predators and scavengers
OPHIUROIDEA Basket stars, brittle stars		Resemble sea stars, but arms long, slender, and more set off from central disc; tube feet used to collect and handle food
ECHINOIDEA Sea urchins, sand dollars		Skeletal plates flattened and fused to form a shell-like test; sand dollars burrow in sand and feed on organic particles; sea urchins graze on algae
HOLOTHUROIDEA Sea cucumbers		Body is elongated, muscular sac; mouth surrounded by tentacles that are modified tube feet; sluggish animals that live on sea bottom; many species eject organs when conditions are poor; for defense, can eject tubules out of anus

(a) **Class Crinoidea.** Feather stars use their slender, jointed appendages to cling to the surface of a rock or coral reef. They can creep away to escape predators.

(b) **Class Asteroidea.** Orange and red sea star (*Fromia monilis*) on a colonial tunicate.

(c) **Class Ophiuroidea.** Daisy brittle star (*Ophiopholis aculeata*), photographed in Muscongus Bay, Maine.

(d) **Class Echinoidea.** With its flattened, circular body, the sand dollar (*Dendraster excentricus*) is adapted for burrowing on the ocean floor. Photographed in Southern California.

(e) **Class Holothuroidea.** A sea cucumber (*Thelonota*) raises its body to spawn.

Figure 32-1 Representative echinoderms

Figure 32-2 Body plan of a sea star

(a) A sea star viewed from above, with its arms in various stages of dissection. Similar structures are present in each arm, but some organs are not shown so as to highlight certain other structures. The two-part stomach is in the central disc with the anus on the aboral (*upper*) surface and the mouth beneath on the oral surface. (b) Cross section through arm and tube feet. (c) LM of underside of a sea star, showing its tube feet.

Basket stars and brittle stars make up the largest group of echinoderms

Basket stars and brittle stars (serpent stars) make up the largest clade of echinoderms (clade *Ophiuroidea*) both in number of species and individuals (see Fig. 32-1c). These animals resemble sea stars in that their bodies consist of a central disc with arms. However, the arms are long and slender and more sharply set off from the central disc than those of sea stars. Some brittle stars use their arms for locomotion, making rowing movements. Their tube feet lack suckers; they may be used to collect and handle food and may also serve a sensory function, perhaps that of taste.

Sea urchins and sand dollars have movable spines

Sea urchins and sand dollars (clade *Echinoidea*) have no arms (see Fig. 32-1d). Their skeletal plates are flattened and fused to form a solid shell called a test. The flattened body of the sand dollar is adapted for burrowing in the sand, where it feeds on tiny organic particles. Sand dollars have smaller spines than sea urchins.

Many sea urchins graze on algae, scraping the sea floor with their calcareous teeth. Sea urchins use their tube feet for locomotion. They also push themselves along with their

movable spines. In some species the spines covering the body can penetrate flesh and are difficult to remove. So threatening are these spines that swimmers on tropical beaches are often cautioned to wear shoes when venturing offshore, where these living pincushions may dwell in abundance.

Sea cucumbers are elongated, sluggish animals

Sea cucumbers (clade *Holothuroidea*) are appropriately named, since some species are about the size and shape of a cucumber. The elongated body is a flexible, muscular sac (see Fig. 32-1e). The mouth is usually surrounded by a circle of tentacles that are modified tube feet. The endoskeleton consists of microscopic plates embedded in the body wall. The circulatory system, which is more highly developed than in other echinoderms, functions to transport oxygen and perhaps nutrients.

Sea cucumbers are sluggish animals that usually live on the bottom of the sea, sometimes burrowing in the mud. Some graze with their tentacles, whereas others stretch their branched tentacles out in the water and wait for dinner to float by. Algae and other morsels are trapped in mucus along the tentacles.

An interesting habit of some sea cucumbers is evisceration, in which the digestive tract, respiratory structures, and gonads

are ejected from the body, usually when environmental conditions are unfavorable. When conditions improve, the lost parts are regenerated. Even more curious, when certain sea cucumbers are irritated or attacked, they direct their rear end toward the enemy and shoot red tubules out of their anus! These unusual weapons become sticky in sea water, and the attacking animal may become hopelessly entangled in the spaghetti-like tangle of tubules. Some of the tubules release a toxic substance.

CHECKPOINT 32.2

- What are three derived characters of echinoderms? Describe each.
- **CONNECT** How do sea stars differ from crinoids? from sea urchins?

32.3 The Chordates: Major Characteristics

LEARNING OBJECTIVE

- 3 Describe characteristics of chordates, including four shared derived characters.

Biologists currently assign the chordates (phylum Chordata) to three clades, or subphyla: urochordates, marine animals called *tunicates*; cephalochordates, marine animals called *lancelets*; and vertebrates, animals with backbones. Although the structures of living species may suggest otherwise, molecular data support that urochordates (not cephalochordates) are the sister group to the vertebrates (FIG. 32-3).

Chordates are deuterostomes. They are coelomates with bilateral symmetry, a tube-within-a-tube body plan, and three well-developed germ layers. Four shared derived characters distinguish the chordates from all other groups of animals. These characters, which evolved in connection with their evolving methods of locomotion and obtaining food, are the notochord; the dorsal, tubular nerve cord; a postanal tail; and an endostyle or thyroid gland (FIG. 32-4).

1. All chordates have a **notochord** during some time in their life cycle. The notochord is a dorsal, longitudinal rod composed of spongy connective tissue cells surrounded by a tough fibrous sheath. The notochord is firm but flexible, and it supports the body. It also plays an important role in embryonic development of the vertebrates.
2. At some time in their life cycle, chordates have a **dorsal, tubular nerve cord**. The chordate nerve cord differs from the nerve cord of most other animals in that it is located dorsally rather than ventrally, is hollow rather than solid, and is single rather than double.
3. Chordates have a larva or embryo with a muscular **postanal tail**, an appendage that extends posterior to the anus.
4. The **endostyle** is a groove in the floor of the pharynx that secretes mucus and traps food particles in the sea water

passing through the pharynx. The endostyle is present in the urochordates, cephalochordates, and lamprey larvae. The thyroid gland evolved from the endostyle and is present in all other chordates.

Pharyngeal slits are another important characteristic of chordates. During chordate embryonic development, a series of grooves develop in the body wall in the region of the pharynx (the part of the digestive tract just posterior to the mouth). A series of outpocketings from the lateral sides of the pharynx (pharyngeal pouches) extend to the grooves. In aquatic chordates the tissue between the grooves and pharyngeal pouches breaks through and forms **pharyngeal slits**, passageways that connect the inside of the pharynx with the surrounding environment.

The perforated pharynx first evolved as an adaptation for filtering food. As water flowed through the mouth and passed out of the pharynx through the pharyngeal slits, suspended food particles were trapped in mucus. Later, modifications evolved, including highly vascularized gills in the passageways. These additions adapted the pharyngeal slits for gas exchange in fishes and some other aquatic vertebrates. Early in vertebrate evolution, anterior pharyngeal arches (supporting tissue between the pharyngeal pouches) evolved into jaws. Although pharyngeal slits are found in all chordates, they are not considered a derived character of chordates because they are also present in hemichordates.

Typically, chordates have an endoskeleton and a closed circulatory system with a ventral heart. Chordates have

Figure 32-3 Evolutionary relationships of the chordates

This cladogram shows hypothesized phylogenetic relationships among deuterostomes based on structural and DNA data.

Key Point

The shared derived characters of chordates include a notochord; dorsal, tubular nerve cord; postanal tail; and endostyle, a groove in the floor of the pharynx that traps food particles in sea water.

Figure 32-4 Generalized chordate body plan

Identify the shared derived characters: notochord; dorsal, tubular nerve cord; postanal tail; and endostyle. Other key characteristics include pharyngeal slits and segmented muscles.

PREDICT What structures do you think the dorsal, tubular nerve cord gives rise to during the development of vertebrate chordates?

segmented bodies, but specialization is so pronounced that the basic segmentation of the body plan may not be apparent. The segmentation is most obvious in the serially repeated body muscles and skeletal structures (like vertebrae), and in the nerves, which supply these tissues.

CHECKPOINT 32.3

- What are four shared derived characters of chordates?
- **CONNECT** How is the chordate nerve cord different from the nerve cord of most other animals?
- **CONNECT** What is the relationship between your jaws and the pharyngeal slits of early chordates?

32.4 Invertebrate Chordates

LEARNING OBJECTIVE

- 4 Compare tunicates and lancelets, and summarize the phylogeny of chordates.

Some chordates are not vertebrates. The invertebrate chordates include tunicates (urochordates) and lancelets (cephalochordates).

Tunicates are common marine animals

The **tunicates**, or **urochordates** (subphylum Urochordata), include the sea squirts and their relatives (**FIG. 32-5**). Larval tunicates have typical chordate characteristics and superficially resemble tadpoles. The expanded body has a pharynx with slits, and the long muscular tail contains a notochord and a dorsal, tubular nerve cord. Some tunicates (*appendicularians*) retain their chordate features and ability to swim. These animals are common members of the zooplankton.

Most tunicates are *ascidians*, commonly known as sea squirts (clade Ascidiacea). A sea squirt larva swims for a time and then attaches itself to a rock, a piling, or the sea bottom. It loses its tail, notochord, and much of its nervous system. Adult sea squirts are barrel-shaped, sessile marine animals unlike other chordates. Indeed, they are often mistaken for sponges or cnidarians. Only the pharyngeal slits, endostyle, and the structure of its larva indicate that the sea squirt is a chordate.

Adult tunicates develop a protective covering, or **tunic**, that may be soft and transparent or quite leathery. Curiously, the tunic consists of a carbohydrate much like cellulose. The tunic has two openings: the incurrent siphon, through which water and food enter; and the excurrent siphon, through which water, waste products, and gametes pass to the outside. Sea squirts get their name from their practice of forcefully expelling a stream of water from the excurrent siphon when irritated.

Tunicates are filter feeders that remove plankton suspended in the stream of water passing through the pharynx. Food particles are trapped in mucus secreted by cells of the endostyle, a groove that extends the length of the pharynx. Ciliated cells of the pharynx move the stream of food-laden mucus into the esophagus. Much of the water entering the pharynx passes out through the pharyngeal slits into an *atrium* (a chamber) and is discharged through the excurrent siphon.

Some species of tunicates form large colonies in which members share a common tunic and excurrent siphon. Colonial forms often reproduce asexually by budding. Sexual forms are typically hermaphroditic; that is, a single individual produces both eggs and sperm.

Lancelets clearly exhibit chordate characteristics

Most **cephalochordates** (subphylum **Cephalochordata**) belong to the genus *Branchiostoma*, which consists of animals commonly known as *lancelets*, or *amphioxus*. Lancelets are translucent, fish-shaped animals, 3 to 8 cm (1.3 to 3.2 in.) long and pointed at both ends. They are widely distributed in shallow seas. Although larvae and adults can swim freely, adults typically burrow in the sand in shallow water near the shore. In some parts of the world, lancelets are an important source of food. One Chinese fishery reports an annual catch of 35 tons (about one billion lancelets).

Chordate characteristics are highly developed in lancelets. The notochord extends from the anterior tip (“head”; hence the name *Cephalochordata*) to the posterior tip. A dorsal, tubular nerve cord also extends the entire length of the animal, and many pairs of pharyngeal slits are evident in the large pharyngeal

(d) Internal structure of a larval tunicate (lateral view).

Figure 32-5 Tunicate body plan

region (FIG. 32-6). Although superficially similar to fishes, lancelets have a far simpler body plan. They do not have paired fins, jaws, sense organs, a heart, or a well-defined head or brain.

Like tunicates, lancelets are filter feeders. Cilia in the mouth and pharynx draw a current of water into the mouth. Microscopic organisms in the water are trapped in mucus secreted by the endostyle and are then moved back to the intestine by beating cilia.

Water passes through the pharyngeal slits into the atrium, a chamber with a ventral opening (the *atriopore*) located anterior to the anus. Metabolic wastes are excreted by segmentally arranged, ciliated *protonephridia* that open into the atrium. Unlike circulation in other invertebrates, the blood flows anteriorly in the ventral vessel and posteriorly in the dorsal vessel in lancelets. This circulatory pattern is similar to that of fishes.

Systematists debate chordate phylogeny

Fossils of early chordates contribute to our understanding of chordate phylogeny. Invertebrate chordates are soft-bodied

and did not leave many fossils. However, some well-preserved, key fossils that date back to the Middle Cambrian have been found in the Burgess Shale of British Columbia, Canada. Early Cambrian fossil sites have been discovered in Chengjiang and Haikou, China. At Chengjiang, fine-grained rocks about 530 million years old have preserved soft-bodied animals, including *Haikouella*, in some detail. *Haikouella* was about 2 to 3 cm (approximately 1 in.) long and had a nerve cord, a notochord, pharyngeal slits, muscle segments, and a brain. Many biologists view *Haikouella* as an early chordate. Some investigators hypothesize that this fossil represents a transitional form between the earliest chordates and the first vertebrates.

Pikaia, a lancelet-like fossil discovered in the Burgess Shale, had a primitive notochord with muscles attached to it that allowed for locomotion. About 4 cm (1.5 in.) in length, *Pikaia* had a tail fin and probably filtered food from the water. *Pikaia* is also considered an early chordate, possibly sharing many similarities with modern cephalochordates.

Figure 32-6 Cephalochordate body plan

(a) Photograph of a lancelet, *Branchiostoma* (amphioxus). Note the prominent pharyngeal slits. **(b)** Longitudinal section showing derived characters and other internal structures.

Are cephalochordates or urochordates the sister group of the vertebrates? Although structural similarities implicated cephalochordates, rather than urochordates, as the sister group to the vertebrates, the predominance of recent molecular data supports that urochordates are the closest relatives of the vertebrates. The molecular data combined with information gathered from available fossils suggest that cephalochordates, urochordates, and vertebrates all evolved from early chordates that had elongated bodies. Some of these very early chordates retained the same general body form and gave rise to the cephalochordates. In others, an adult that was sessile, rather than swimming, gave rise to the urochordates. A third lineage added a number of specialized features while giving rise to the vertebrates.

The tunicate *Ciona intestinalis* is an excellent model organism for studying chordate genetics and development because its genome consists of only about 16,000 protein-coding genes, the basic set of genes found in chordates. Interestingly, about 80% of *Ciona*'s genes are found in vertebrates. In fact, *Ciona* has most vertebrate gene families, but in simplified form. For example, *Ciona* has only a single copy of each gene family involved in cell signaling and regulation of development, whereas vertebrates have two or more copies of these gene families. (A gene family is a group of genes that evolved over time from a single ancestral gene through duplication and divergence.) Some of the “extra” copies probably evolved to code for new structures or functions. *Ciona* also has genes for some vertebrate structures and processes, even though it does not express these genes.

CHECKPOINT 32.4

- **CONNECT** How are the main derived chordate characters evident in a tunicate larva and in an adult tunicate?
- **CONNECT** If you found a small fishlike animal along the shoreline, how would you determine whether or not it was a lancelet?

32.5 Introducing the Vertebrates

LEARNING OBJECTIVES

- 5 Describe four shared derived characters of vertebrates.
- 6 Describe the major taxa of extant vertebrates.

Numbering about 50,000 described species, the **vertebrates** (subphylum Vertebrata) are less diverse and much less numerous than the insects. However, vertebrates rival the insects in their adaptations to an enormous variety of lifestyles (**FIG. 32-7**). In addition to the basic chordate characteristics, vertebrates have a number of shared derived characters not found in other groups.

The vertebral column is a derived vertebrate character

The vertebrates are distinguished from other chordates in having a **vertebral column** that forms the skeletal axis of the body. Although sometimes called the “backbone,” the vertebral column actually consists of a series of separate skeletal elements, the *vertebrae*, which are made of cartilage or bone. This flexible support develops around the notochord, and in most species it largely replaces the notochord during embryonic development. Dorsal projections of the vertebrae enclose the nerve cord along its length. Anterior to the vertebral column, a cartilaginous or bony **cranium**, or braincase, encloses and protects the brain, the enlarged anterior end of the nerve cord.

The cranium and vertebral column are part of the **endoskeleton**. In contrast with the nonliving exoskeleton of many invertebrates, the vertebrate endoskeleton is a living tissue that grows with the animal. Some vertebrates (jawless and cartilaginous fishes) have skeletons made of cartilage. However, in most vertebrates the skeleton is mainly bone, a tissue that contains fibers made of the protein collagen. The hard matrix of bone consists of the compound hydroxyapatite,

Key Point

This cladogram provides a framework for understanding the evolution of vertebrate diversity and adaptations to aquatic and terrestrial environments.

Figure 32-7 Evolutionary relationships of extant vertebrates

This cladogram represents one phylogenetic interpretation of vertebrate phylogeny. The evolution of certain key characters is indicated. As new data are collected and considered, details of the cladogram will likely change. Amniote relationships are shown in more detail in Figure 32-20.

CONNECT What are some advantages of the pronounced cephalization that occurred as vertebrates evolved from jawless fish to tetrapods?

composed mainly of calcium phosphate. Muscles are attached to the endoskeleton.

Many characters common to vertebrates have been derived from a group of embryonic cells called **neural crest cells**. These cells, found only in vertebrates, appear early in development and migrate to various parts of the embryo. Neural crest cells give rise to or influence the development of many structures, including nerves, head muscles, cranium, and jaws.

Recall that *Hox* genes are important in determining pattern development in embryos (see Chapter 17). Specifically, *Hox* genes determine the fate of cells in the anterior–posterior axis. These genes occur in clusters on specific chromosomes. Invertebrates and nonvertebrate chordates that have been studied have one *Hox* gene cluster. As a result of gene duplication, vertebrates have several duplicated clusters. Some species of fish have up to eight duplicated clusters of *Hox* genes. Mammals have four sets of *Hox* genes.

Other gene clusters, including some encoding transcription factors and others coding globin proteins for transporting oxygen, were also duplicated during the evolution of the early vertebrates. The significance of these genetic changes is the focus of investigation. It is reasonable, however, to hypothesize that the increase in genetic complexity contributed to the evolution of more complex and varied bodies.

Recall that some invertebrate groups show an evolutionary trend toward **cephalization**, the concentration of nerve cells and sense organs in a definite head. The vertebrates are characterized by *pronounced* cephalization. The brain has become larger and more elaborate, and its various regions have specialized to perform different functions. Either 10 or 12 pairs of **cranial nerves** emerge from the brain and extend to various organs of the body. Vertebrates have well-developed sense organs concentrated in the head: eyes; ears that serve as organs of balance and, in some vertebrates, for hearing as well; and organs of smell and taste.

Most vertebrates have two pairs of appendages. The fins of fishes are appendages that stabilize and/or help propel the fish in the water. Paired pectoral and pelvic fins are also used in steering. Based on structural, molecular, and fossil data, biologists hypothesize that jointed appendages that facilitated locomotion on land (i.e., legs) evolved from the lobed fins of lungfishes.

Vertebrates have a closed circulatory system with a ventral heart and blood containing hemoglobin. The complete digestive tract has specialized regions and large digestive glands (the liver and pancreas). Several *endocrine glands*, which are ductless glands, secrete hormones. Paired kidneys regulate fluid balance. The sexes are typically separate.

Early vertebrates were probably marine animals. In contrast to the tunicates and lancelets, which use cilia to beat a stream of water into the mouth and filter particles of food from the water, vertebrates use muscles for feeding. Some vertebrates use muscles to draw in a current of water from which both food and oxygen can be extracted. Muscles in the wall of the digestive tube are more powerful than cilia and probably contributed to an increase in both size and activity of early vertebrates. A muscular pharynx with firm skeletal elements for support may have permitted animals to crush small prey after capture. The evolution of more effective sensory systems, a more complex brain, and organs that could support increased activity was important in the shift from filter-feeding to a more active lifestyle.

Vertebrate taxonomy is a work in progress

The evolutionary relationships of vertebrates are an important focus of research. The earliest vertebrate fossils include *Haikouichthys*, conodonts, and a group known as *ostracoderms* (discussed in the next section). *Haikouichthys* was a fishlike animal about 2.5 cm (1 in.) long. It had several characters found in vertebrates, and some researchers think it was an early jawless fish.

Conodonts were simple fishlike chordates with gill arches (tissues that support the gills), muscular segments, and fins. They had large eyes and complex toothlike hooks that were probably used in capturing prey. Conodonts were abundant from the Precambrian to the Late Triassic period; they have

been identified in several fossil beds around the world. Cladistic analyses suggest that conodonts were early vertebrates.

By the Late Cambrian, the chordates included a number of different taxa with skeletal elements (a rudimentary braincase, or cranium) protecting the brain. Some of these animals also showed evidence of vertebrae. These earliest vertebrates lacked jaws and are sometimes referred to as **agnathans** (*a*, “without”; and *gnathos*, “jaw”).

The extant vertebrates can be assigned to nine clades (classes): six clades (classes) of fishes and three of **tetrapods** (four-limbed vertebrates) (TABLE 32-2; see also Fig. 32-7). Most modern biologists classify the tetrapods as *Tetrapoda* (including amphibians and amniotes) and *Amniota* (including the animals traditionally called reptiles, birds, and mammals). The extant amphibian clade includes frogs, toads, salamanders, newts, and caecilians; the extant reptilian clade includes lizards, snakes, turtles, alligators, and birds.

CHECKPOINT 32.5

- **CONNECT** What shared derived characters distinguish the vertebrates from the rest of the chordates?
- What are the main clades (classes) of fishes? the main groups of tetrapods?

32.6 Jawless Fishes

LEARNING OBJECTIVE

- 7 Distinguish among the major groups of jawless fishes.

Some of the earliest known vertebrates, collectively referred to as **ostracoderms**, consisted of several groups of small, armored, jawless fishes that lived on the bottom and strained their food from the water (see Fig. 21-11). Thick bony plates protected their heads from predators, and thick scales covered their trunks and tails. Most ostracoderms lacked paired fins. Fragments of ostracoderm scales have been found in rocks from the Cambrian period, but most ostracoderm fossils are from the Ordovician and Silurian periods. They became extinct by the end of the Devonian period.

Like ostracoderms, present-day hagfishes and lampreys have neither jaws nor paired fins. They are eel-shaped animals, up to 1 m (about 3 ft) long. Their smooth skin lacks scales, and they are supported by a cartilaginous skeleton and well-developed notochord.

Hagfishes, clade *Myxini* (mik-sin'y), are marine scavengers (FIG. 32-8). They burrow for worms and other invertebrates or prey on dead and disabled fishes. Hagfishes use toothlike projections from their tongue to pull off flesh from prey. For leverage, a hagfish can tie itself into a knot. As a defense mechanism, hagfishes secrete large amounts of fluid that forms sticky slime in sea water. The hagfish becomes so slippery that predators cannot grasp it.

In the past, some systematists argued that the hagfishes did not quite qualify as vertebrates. Although they have many vertebrate characteristics, including a cranium, they were thought

Table 32-2 Extant Vertebrate Clades (Classes)

Clade		Examples	Characteristics
MYXINI		Hagfishes	Jawless, marine fishes that lack paired appendages; the notochord is their only axial support
PETROMYZONTIDA		Lampreys	Jawless, freshwater and marine fishes with skeleton of cartilage; complete cranium and rudimentary vertebrae; gills; specialized sense organs
CHONDRICHTHYES		Sharks, rays, skates, chimaeras	Jawed marine and freshwater fishes with skeleton of cartilage; vertebrae present; gills; placoid scales; two pairs of fins; oviparous, ovoviviparous, or viviparous (a few species); well-developed sense organs
ACTINOPTERYGII (ray-finned fishes)		Perch, salmon, tuna, trout	Bony, marine and freshwater fishes; gills; swim bladder; generally oviparous
ACTINISTIA (fleshy-finned fishes)		Coelacanths	Bony fishes; marine, nocturnal predators on fish; lobed fins
DIPNOI (fleshy-finned fishes)		Lungfishes	Bony freshwater fishes; have both functional gills and lungs
AMPHIBIA		Salamanders, frogs and toads, caecilians	Aquatic larva typically undergoes metamorphosis into terrestrial adult; gas exchange through lungs and/or moist skin; two atria and single ventricle; systemic and pulmonary circulation
REPTILIA		Turtles, lizards, snakes	Amniotes with horny scales; adapted for reproduction on land (internal fertilization, leathery shell, amnion); lungs; ventricles of heart partly divided
		Crocodylians and birds	Amniotes with two complete ventricles; care for their young. Birds have feathers; anterior limbs modified as wings; compact, endothermic; vocal calls and complex songs
MAMMALIA		Monotremes (Protheria), marsupials (Metatheria), mammals with well-developed placentas (Eutheria)	Amniotes with hair; females nourish young with mammary glands; differentiation of teeth; three middle-ear bones; diaphragm; heart with two separate atria and two separate ventricles; endothermic; highly developed nervous system

to lack any trace of vertebrae. However, more recently they have been shown to have rudimentary vertebrae. Hagfishes and lampreys are now classified as vertebrates and viewed as sister groups.

Lampreys, clade Petromyzontida (pet-tro-my-zon'-tih-da; from the Greek *petros*, “stone,” and *myzon*, “sucking”), are jawless vertebrates. Lampreys hold onto stones by their mouths to prevent being washed away by the currents. Some lampreys spend their adult lives in the ocean and return to fresh water to reproduce. Many species of adult lampreys are parasites on other fishes (FIG. 32-9). Adult parasitic lampreys have a circular sucking disc around the mouth, which lies on the ventral side of the anterior end of the body. Using this disc to attach to a fish, the lamprey bores through the skin of its host with horny teeth (made

of keratin) on the disc and tongue. Then the lamprey injects an anticoagulant into its host and sucks out blood and soft tissues.

As in hagfish, the notochord persists throughout life and is not replaced by a vertebral column. Lampreys have rudiments of vertebrae, cartilaginous segments that extend dorsally around the spinal cord.

CHECKPOINT 32.6

- **CONNECT** How do lampreys and hagfishes resemble ostracoderms?

Figure 32-8 Pacific hagfish (*Eptatretus stoutii*)

The hagfish has a flexible body, which it can tie into knots. It knots its tail and then slides the knot toward its head. Being knotted gives it leverage when tearing flesh from its prey. Knotting itself also helps the hagfish remove excess slime from its body.

32.7 Evolution of Jaws and Limbs: Jawed Fishes and Tetrapods

LEARNING OBJECTIVE

- 8** Trace the evolution of jawed fishes and early tetrapods, and describe modern amphibians.

Imagine trying to hunt for food and then eat without jaws or limbs. Such was the challenge for early vertebrates, which

helps explain why the jawless fishes are mainly scavengers and parasites. The evolution of jaws from a portion of the gill arch skeleton and the development of fins allowed fishes to become active predators. With jaws an animal can grasp and hold on to live prey while eating it. The evolution of fins allowed fishes to swim faster and with more control. Fishes with jaws and fins had many new opportunities for capturing food.

Fossil evidence suggests that jaws and paired fins evolved during the Late Silurian and Devonian periods. Two early groups of jawed fishes, now extinct, were the **acanthodians**, armored fishes with paired spines and pectoral and pelvic fins, and **placoderms**, armored fishes with paired fins (FIG. 32-10). Vertebrates with jaws are referred to as **gnathostomes** (nath'-o-stomes). The success of the jawed vertebrates probably contributed to the extinction of the ostracoderms.

When the fins of certain fishes evolved into limbs about 370 mya, a different type of locomotion was possible. These limbed vertebrates (early tetrapods) were able to move about in shallow waters and wetlands in search of food. Some of these early tetrapods were able to move on land and gained access to new food and habitats.

Most cartilaginous fishes inhabit marine environments

The cartilaginous fishes, members of clade **Chondrichthyes** (kon-drik'-thee-eez), appeared as successful marine forms in the Devonian period. Chondrichthyes are a monophyletic group that includes the sharks, rays, skates, and ratfishes (FIG. 32-11). Most species are ocean dwellers, but a few have invaded fresh water. With the exception of whales, the sharks are the largest living vertebrates. Some whale sharks (*Rhincodon*) exceed 15 m (49 ft) in length.

(a) Lampreys (*Petromyzon marinus*) attached to carp (*Cyprinus* sp.) by their suction-cup mouths. Note the absence of jaws and paired fins.

(b) Suction-cup mouth of adult lamprey (*Entosphenus japonicus*). Note the rasplike teeth.

Figure 32-9 Lampreys

Parasitic lampreys attach to fish and suck out body fluids. They leave wounds in the fish that may be fatal.

(a) An **acanthodian**. *Climatius* was a spiny-skinned acanthodian with large fin spines and five pairs of accessory fins between the pectoral and pelvic pairs. *Climatius* was a small fish that reached a length of 8 cm (3 in.).

(b) A **placoderm**. *Dunkleosteus* was a giant placoderm that grew to a length of 8 m (26 ft). (Most placoderms were only about 20 cm [8 in.] long.) Its head and thorax were covered by bony armor, but the rest of the body and tail were naked.

Figure 32-10 Early jawed fishes

Acanthodians and placoderms flourished in the Devonian period.

Most rays and skates are flattened creatures that live partly buried in the sand. Their enormous pectoral fins propel them along the bottom, where they feed on mussels and clams. The stingray has a whiplike tail with a barbed spine at its base that can inflict a painful wound. The electric ray has electric organs on either side of the head. These modified muscles can discharge enough electric current (up to 200 volts) to stun fairly large fishes as well as human swimmers.

Chondrichthyes retain their cartilaginous embryonic skeleton. Although this skeleton is not replaced by bone, in many species calcium salts are added to the cartilage for strength. All chondrichthyes have jaws and two pairs of fins (FIG. 32-12). The skin contains **placoid scales**, which are tooth-like structures. The lining of the mouth contains larger, but essentially similar, scales that serve as teeth. The teeth of other vertebrates are homologous with these scales. Shark teeth are embedded in the flesh and not attached to the jawbones; new teeth develop continuously in rows behind the functional teeth and migrate forward to replace any that are lost.

The streamlined shark body is adapted for rapid swimming. Lift is provided by body shape and fins. The shark stores a great deal of oil in its large liver (which may account for up to 30% of its body weight). Fats and oils decrease the overall density of fishes and contribute to buoyancy. Even so, the shark body is denser than water, so sharks tend to sink unless they are actively swimming.

Most sharks are predators that swim actively and prey on other fishes as well as on crustaceans and mollusks. The largest sharks and rays, like the largest whales, are filter feeders that strain plankton from the water. They gulp water through the mouth. As the water passes through the pharynx and out the gill slits, food particles are trapped in a sievelike structure.

Predatory sharks are attracted to blood, so a wounded swimmer or a skin diver towing speared fish is a target. However, despite the common portrayal of sharks in books and

(a) **Blue-spotted stingray** (*Taeniura lymma*). Stingrays typically feed on shellfish and bottom-dwelling fishes.

(b) **Great white shark** (*Carcharodon carcharias*). Photographed at Neptune Islands, Spencer Gulf, South Australia, this shark is considered the most dangerous shark to humans. It is actually white only on its ventral aspect; the rest of the body is brownish gray or bluish gray.

Figure 32-11 Cartilaginous fishes

films as monstrous enemies, most do not go out of their way to attack humans. In fact, of the approximately 350 known shark species, fewer than 30 are known to attack humans.

Sharks have a complex brain and a spinal cord that is protected by vertebrae. Their well-developed sense organs effectively locate prey in the water. Sharks may detect other animals electrically in addition to sensing them by sight or smell.

Electroreceptors on the shark's head sense weak electric currents generated by the muscle activity of animals. The **lateral line organ**, found in all fishes and many amphibians, is a groove along each side of the body with many tiny openings to the outside. Sensory cells in the lateral line organ detect vibrations caused by waves and other movement in the water, including movements by predators or prey (see Fig. 43-7).

Cartilaginous fishes have no lungs. Gas exchange takes place through their five to seven pairs of gills. A current of water enters the mouth and passes over the gills and out the pharyngeal slits, constantly providing the fish with a fresh supply of dissolved oxygen. Sharks that actively swim depend on their motion to enhance gas exchange. Rays, skates, and sharks that spend time on the ocean floor use muscles of the jaw and pharynx to pump water over their gills.

(a) Internal structure of a shark.

(b) Placoid scales. These tough scales protect the shark against predators. The base of each placoid scale is embedded in the skin. Placoid scales are toothlike structures. They are covered with hard enamel.

(c) Teeth. Placoid scales are embedded in the flesh along the inner surface of the jaw cartilage where they function as teeth. Sharks have several rows of teeth. Old teeth are shed and quickly replaced.

Figure 32-12 Anatomy of a shark

The digestive tract of sharks consists of the mouth cavity; a long pharynx leading to the stomach; a short, straight intestine; and a **cloaca** (klow-a'-kuh), which opens on the underside of the body. (The cloaca is characteristic of many vertebrates; see Fig. 32-12.) The liver and pancreas discharge digestive juices into the intestine. The cloaca receives digestive wastes as well as metabolic wastes from the urinary system. In females the cloaca also serves as a reproductive organ.

The sexes are separate, and fertilization is internal. In the mature male, each pelvic fin has a slender, grooved section, known as a *clasper*, used to transfer sperm into the female's cloaca. The eggs are fertilized in the upper part of the female's oviducts. Part of the oviduct is modified as a shell gland, which secretes a protective coat around each egg.

Skates and about 30% to 40% of sharks, including zebra sharks, are **oviparous**. They lay eggs. After fertilization, the eggs are laid, typically within a leathery pouch. Other species of sharks, including nurse sharks and great white sharks, are **ovoviviparous**. Their young are enclosed in eggs and incubated within the mother's body. During development, the young depend on stored yolk for their nourishment rather than on transfer of materials from the mother. The young are born after hatching from the eggs.

Some species of sharks, including hammerhead sharks and blue sharks, are **viviparous**. Not only do the embryos develop within the uterus, but nutrients and oxygen from blood vessels in the uterus are delivered to them by the mother's blood. After a gestation period of up to 3 years, the young sharks are born alive.

Ray-finned fishes gave rise to modern bony fishes

Although bony fishes appear earlier in the fossil record than cartilaginous fishes, both groups may have evolved about the same time, during the Late Silurian or Early Devonian period. The two groups share many characteristics (such as continuous tooth replacement), but they also differ in important ways.

Most bony fishes are characterized by a bony skeleton with many vertebrae. Bone has advantages over cartilage because it provides excellent support and effectively stores calcium. Most species have flexible median and paired fins supported by long rays made of cartilage or bone. Overlapping, bony dermal scales cover the body. A lateral bony flap, the **operculum**, extends posteriorly from the head and protects the gills.

Most bony fishes are oviparous. Most species lay an impressive number of eggs and fertilize them externally. The

ocean sunfish, for example, lays more than 300 million eggs! Of course, most of the eggs and young become food for other animals. The probability of survival is increased by certain behavioral adaptations. For example, many species of fishes build nests for their eggs and protect them. Other species have internal fertilization and give birth to live young.

During the Devonian period, the bony fishes diverged into two major groups: the fleshy-finned fishes, *Sarcopterygii*; and the **ray-finned fishes** (clade *Actinopterygii*). Fossils of the earliest sarcopterygians date back to the Devonian period, about 400 mya. Lungs and fleshy, *lobed fins* characterized these fishes. The flexible fins were supported by thin, bony rays radiating out from a thick base of multiple bones and muscles. Lobed fins may have evolved as an adaptation for pushing along the bottom of any body of water.

Early sarcopterygians evolved along three separate lines: the *lungfishes* (clade *Dipnoi*), the *coelacanth*s (clade *Actinistia*), and the *Tetrapodomorpha*, a clade consisting of tetrapods and their most recent ancestors. All three lineages had fins with fleshy bases of muscle and bone. Surviving from these groups today are three genera of lungfishes, two species of *coelacanth*s, and the many thousands of species of tetrapods (amphibians and amniotes) in habitats worldwide.

Although the earliest ray-finned fishes also had both lungs and gills, they differed from the sarcopterygians in having more flexible fins with less bone and muscle at the base. The ray-finned fishes (actinopterygians) underwent two important adaptive radiations. The first gave rise during the Late Paleozoic era to a group of fishes that are now mostly extinct. The second radiation began during the Early Mesozoic era and gave rise to the very successful modern bony fishes.

In addition to gills, the common ancestor of the bony fishes had primitive lungs that could exchange gases in air. Lungs for gas exchange were retained by the tetrapods and lungfishes. In the modern ray-finned fishes, the lungs became modified as a **swim bladder**, an air sac that helps regulate buoyancy (FIG. 32-13). Bones and muscles are heavier than water, and without the swim bladder, the fish would sink. By regulating gas exchange between its blood and swim bladder, a fish can control the amount of gas

in the swim bladder and thus change the overall density of its body. This ability allows a bony fish, in contrast to a shark, to hover at a given depth of water without much muscular effort.

There are more species of bony fishes than of any other vertebrate group. Biologists have identified tens of thousands of living species of freshwater and saltwater bony fishes, of many shapes and colors (FIG. 32-14). Bony fishes range in size from that of *Paedocypris progenetica*, which has been measured at less than 8 mm (about 0.3 in) long, to that of the ocean sunfish (*Mola mola*; see Fig. 20-16c), which may reach 4 m (13 ft) and weigh about 1500 kg (about 3300 lb). *Paedocypris progenetica*, native to Indonesia, is the smallest known vertebrate.

The diversity of bony fishes may have resulted from the action of *Hox* genes. During the radiation of ray-finned fishes, entire chromosomes duplicated, resulting in one or more additional clusters of *Hox* genes. The zebrafish (see Fig. 17-6d) has seven *Hox* clusters. These additional genes could have provided the genetic material for the evolution of the diverse species of ray-finned fishes.

Tetrapods evolved from sarcopterygian ancestors

Biologists thought that the **coelacanth**s were extinct by the end of the Paleozoic era, so in 1938 the scientific community was very excited when a commercial fisherman caught one off the coast of South Africa. Since that time, more than 200 specimens of these giant “living fossils” have been found in the deep waters off the southeastern coast of Africa, near the Comores Islands in the Indian Ocean, and off the coasts of Madagascar and Indonesia (FIG. 32-15). These coelacanth, which measure nearly 2 m (about 6 ft) in length, are nocturnal predators on other fishes.

The relationships among the three living groups of sarcopterygians (coelacanth, lungfishes, and tetrapods) have been investigated for many years. Although it was known that the tetrapods evolved from the fleshy-finned fishes, it was not known whether the lungfishes or the coelacanth were the nearest relatives of this group. Fossil evidence and DNA analyses support the lungfishes as the sister group to the tetrapods (FIG. 32-16).

Figure 32-13 Perch, a representative bony fish

The swim bladder is a hydrostatic organ that enables the fish to change the density of its body and remain stationary at a given depth. Pectoral fins (not shown) and pelvic fins are paired.

Peter Scones/Taxi/Getty Images

Figure 32-15 Coelacanth

Although they were more diverse and widespread during their early history, the coelacanths, like this *Latimeria chalumnae*, are restricted today to certain deep sea environments.

Molecular data support the structural evidence that the limbs of tetrapods evolved from the lobed fins of fishes. Proteins encoded by certain regulatory genes, including *Hox* genes, have been found at the same developmental times and in the same locations in both limbs and fins. These findings indicate that limb and fin development are governed by the same genes.

What drove the evolution of tetrapod limbs? One hypothesis suggests that during the frequent seasonal droughts of the Devonian period, swamps became stagnant or dried up completely. Fishes with lobed fins had a tremendous advantage for survival under those conditions. They were strikingly preadapted for moving onto the land. They had lungs for breathing air, and their sturdy, fleshy fins allowed them to "walk" along in shallow water. These fins could support the fish's weight, so it could emerge onto dry land and make its way to another pond or stream.

A more recent hypothesis holds that limbs evolved in a fully aquatic environment. Animals with more-developed limbs could move along in shallow water or creep through dense aquatic vegetation more efficiently than their lobe-finned ancestors. *Tiktaalik* was a transitional form between fishes and tetrapods (FIG. 32-17).

Perennou Nuridsany/Science Source

Figure 32-16 South American lungfish (*Lepidosiren paradoxus*)

Lungfishes were common in Devonian and Carboniferous times (400 mya to 300 mya). South American lungfish have paired lungs on either side of the throat and can survive for long periods if the river they inhabit dries up.

Biologists consider *Tiktaalik*, which lived about 375 mya (during the Devonian period), a fish because it had scales, fins, gills, and lungs. However, *Tiktaalik* also had tetrapod features such as a movable neck and ribs that supported lungs.

Acanthostega was one of the earliest known tetrapods. Fossils from the Devonian period show that this animal had four legs with well-formed digits. However, because its limbs were not properly positioned for walking effectively on land and because it possessed gills and a tail fin, *Acanthostega* was a fully aquatic tetrapod. The ichthyostegids, tetrapods known from somewhat later in the Devonian, had more robust limbs and girdles, suggesting that they could move more easily on land. However, the evidence suggests that these early tetrapods were also very aquatic.

Those early tetrapods that could explore shallow wetlands and make their way onto dry land had access to new food sources. Terrestrial plants were already established, and terrestrial insects and arachnids were rapidly evolving. A vertebrate

Zina Deretsky/National Science Foundation

Figure 32-17 *Tiktaalik*

This extinct fish, which grew to 2.75 m (9 ft), had limblike fins and other tetrapod features.

that could survive on land had less competition for food than one that was solely aquatic. However, success on land required the evolution of several major adaptations in addition to legs.

As discussed, the early sarcopterygians had lungs for gas exchange in addition to gills. Lungs were important because gills cannot function in air. Life on land also required changes in the muscles and skeleton to support the body's weight in air. Body coverings and other mechanisms were needed to protect animals against the drying effect of air.

Evolution of ears that could hear sound transmitted through air and olfactory mechanisms for detecting airborne odors contributed to the ability to find food and mates, and to avoid predators. It is likely that early tetrapods needed to return to the water for reproduction, but eventually adaptations evolved that allowed some animals to reproduce in terrestrial environments. The early tetrapods were very successful and eventually gave rise to the amphibians and the amniotes (including reptiles, birds, and mammals).

Amphibians were the first successful land vertebrates

Biologists classify modern **amphibians** (*Amphibia*) in three clades. *Caudata* ("with tail") includes salamanders, mud puppies, and newts, all animals with long tails. *Anura* ("no tail") is made up of frogs and toads, most with legs adapted for hopping. *Gymnophiona* contains the limbless caecilians (**FIG. 32-18**). Although some adult amphibians are quite successful as land animals and live in dry environments, most must return to the water to reproduce. Eggs and sperm are typically released in the water.

Many amphibians undergo **metamorphosis**, a transition from larva to adult. The embryos of most frogs and toads develop into larvae called *tadpoles*. These larvae have tails and gills, and most feed on aquatic plants. After a time, the tadpole undergoes metamorphosis, which is regulated by hormones secreted by the *thyroid gland*. During metamorphosis, gills and gill slits disappear, the tail is resorbed, and limbs emerge. The digestive tract shortens, and food preference shifts from plant material to a carnivorous diet; the mouth widens; a tongue develops; the tympanic membrane (eardrum) and eyelids appear; and the eye lens changes shape. Many biochemical changes accompany the transformation from a completely aquatic life to a semiterrestrial one.

Several salamanders, such as the mudpuppy *Necturus*, do not undergo complete metamorphosis; they retain many larval characteristics even when sexually mature adults. Recall from Chapter 20 that this retention of juvenile features is called **paedomorphosis** (see Fig. 20-17). This type of development permits these salamanders to remain aquatic rather than having to compete on land.

The coloration of amphibians may conceal them in their habitat or may be very bright and striking. Many of the brightly colored species are poisonous (see Fig. 32-18). Their distinctive colors warn predators that they are not encountering an ordinary amphibian. Some frogs camouflage themselves by changing color.

Adult amphibians do not depend solely on their primitive lungs for the exchange of respiratory gases. Their moist, glandular skin, which lacks scales and is plentifully supplied

(a) **Adult strawberry poison frog (*Dendrobates pumilio*)**. Poison dart frogs, native to Central America and South America, are active during the day. Most are brightly colored. Many secrete toxins through their skin as a chemical defense against predators. Photographed in Bastimentos National Park, Bocas del Toro, Panama.

(b) **Fire salamander (*Salamandra atra*)**. Fire salamanders are well known in Europe. Their poison glands release neurotoxins.

Figure 32-18 Modern amphibians

with blood vessels, also serves as a respiratory surface. The numerous mucous glands within the skin help keep the body surface moist, which is important in gas exchange. The mucus also makes the animal slippery, facilitating its escape from predators. Most amphibians have glands in their skin that secrete toxic and/or foul-tasting substances that repel predators.

The amphibian heart contains two **atria** (sing. *atrium*), receiving blood, and a single **ventricle**, pumping blood into the arteries. A double circuit of blood vessels keeps oxygen-rich and oxygen-poor blood partially separate. Blood passes through the **systemic circulation** to the various tissues and organs of the body. Then, after returning to the heart, it is directed through the **pulmonary circulation** to the lungs and skin, where it is recharged with oxygen. The oxygen-rich blood returns to the heart to be pumped out into the systemic circulation again. We discuss the comparative anatomy of the heart and circulation of various vertebrate clades in Chapter 44.

CHECKPOINT 32.7

- **CONNECT** From an evolutionary perspective, what is the significance of each of the following: (1) placoderms, (2) lungfishes, (3) ray-finned fishes, and (4) *Tiktaalik*?
- What changes allow amphibians to move from aquatic life as a tadpole to terrestrial life as an adult?

32.8 Amniotes: Terrestrial Vertebrates

LEARNING OBJECTIVES

- 9 Describe three vertebrate adaptations to terrestrial life.
- 10 Describe the reptiles (including the birds) and argue for including the birds in the reptile clade.
- 11 Describe five key characters of mammals and contrast protherian (monotremes), metatherian (marsupials), and eutherian mammals, giving examples of animals that belong to each group.

The evolution of **reptiles** from ancestral amphibians required many adaptations that allowed them to become completely terrestrial. Evolution of the **amniotic egg** was an extremely important event because it allowed terrestrial vertebrates to complete their life cycles on land. The amniotic egg contains an **amnion**, a membrane that forms a fluid-filled sac around the embryo. The amnion provides the embryo with its own private “pond,” permitting independence from a watery external environment. In addition to keeping the embryo moist, the amniotic fluid serves as a shock absorber that cushions the developing embryo.

The evolution of the amniotic egg is so important to the success of terrestrial vertebrates—reptiles (including birds) and mammals—that biologists refer to these animals as **amniotes**. Amniotes are a monophyletic group because they have a recent common ancestor that was itself an amniote.

In addition to the amnion, the amniotic egg has three other extraembryonic (not part of the developing body itself) membranes: *yolk sac*, *chorion*, and *allantois* (FIG. 32-19). These membranes protect the developing embryo, store nutrients (yolk sac), carry on gas exchange (chorion, allantois, and yolk sac), and store wastes (allantois). We discuss development of the extraembryonic membranes in Chapter 51. Although most extant mammals do not lay eggs, their embryos have an amnion and other extraembryonic membranes.

Another important adaptation to terrestrial life is a body covering that minimizes water loss. The amniote body covering is typically thick and contains **keratin**, a water-insoluble protein that helps protect the animal from injury. Keratin is found in the epidermis and in derivatives of the epidermis, such as scales, nails, feathers, hair, and horns. A body covering containing keratin presents another challenge: it severely decreases gas exchange across the body surface. This challenge has been met by the evolution of efficient lungs and circulatory systems for exchange of oxygen and

Figure 32-19 An amniotic egg

The amnion, a fluid-filled sac surrounding the embryo, keeps the embryo moist and protects it from mechanical shock. Other extra-embryonic membranes include the yolk sac, which functions in nutrition; the allantois, which stores metabolic wastes; and the chorion, which along with the allantois, functions in gas exchange.

carbon dioxide. Amniotes also have physiological mechanisms for conserving water. For example, much of the water filtered from the blood by the kidneys is reabsorbed in the kidney tubules to decrease fluid loss during excretion of metabolic wastes.

Our understanding of amniote phylogeny is changing

Biology instructors once taught that the three main groups (classes) of amniotes were Reptilia, Aves (birds), and Mammalia. However, cladistic analysis determined that class Reptilia was not a monophyletic group without the birds. Because it included some, but not all, of its descendants, it was paraphyletic (see Fig. 23-7). For this reason, biologists now classify the birds as a group of reptiles.

Biologists hypothesize that the earliest amniotes resembled lizards. By the Late Carboniferous period, about 290 mya, amniotes had undergone an impressive adaptive radiation and had diverged into two main branches: **diapsids** and **synapsids** (FIG. 32-20 and TABLE 32-3). The term *diapsid* refers to the two pairs of openings in the temporal bones that characterize the skulls of these animals. Synapsid skulls have one pair of temporal openings. The diapsids comprise all extant reptilian groups, including the birds and most extinct reptiles. The synapsids include the extinct **therapsids** and the mammals.

A second great adaptive radiation of amniotes occurred during the Mesozoic era, which ended about 66 mya. During that time reptiles were the dominant terrestrial vertebrates (see Chapter 21). In fact, the Mesozoic era is known as the “Age of Reptiles.” Reptiles had radiated into an impressive variety of ecological lifestyles (see Figs. 21-13, 21-14, and 21-15). Some could fly, others became marine, and many filled terrestrial habitats. Among the major groups were the *pterosaurs* (ter'-uh-sawr), the flying reptiles; the *saurischian dinosaurs* (saw-ris'-kee-un), a group that included *Tyrannosaurus* and *Diplodocus*; and the *ornithischian dinosaurs* (awr-nuh-this'-kee-un), including *Triceratops*.

Some of the dinosaurs were among the largest land animals to ever walk on Earth. Some dinosaurs apparently traveled in

social groups and took care of their young. Fossil evidence supports the hypothesis that at least some dinosaurs may have been **endotherms**, meaning that they used metabolic energy to maintain a constant body temperature despite changes in the temperature of the environment. An advantage of endothermy is that it allows animals to be more active. The natural history and evolution of dinosaurs and other early reptiles are discussed in more detail in Chapter 21.

The reptiles were the dominant land vertebrates for almost 200 million years. Then, toward the end of the Mesozoic era, many reptiles, including all the dinosaurs and pterosaurs, disappeared from the fossil record. In fact, more than half of all animal species became extinct at that time (see Chapter 21).

Reptiles have many terrestrial adaptations

Many reptilian characters are adaptations to terrestrial life. The female reptile secretes a protective leathery shell around the egg, which helps prevent the developing embryo from drying out. The shell presents a challenge for reproduction because sperm cannot penetrate it. Fertilization must take place within the body of the female before the shell is added. In this process, the male uses a copulatory organ (penis) to transfer sperm into the female reproductive tract. An amnion surrounds the embryo as it develops within the protective shell.

The hard, dry, keratin scales that are part of the reptile's skin retard drying in yet another adaptation to life on land. This scaly protective armor, which also protects the reptile from predators, is shed periodically. The dry reptilian skin does not allow effective gas exchange. Reptilian lungs are better developed than the saclike lungs of amphibians. Divided into many chambers, the reptilian lung provides an increased surface area for gas exchange.

The hearts of amniotes contain two atria. The ventricle of reptiles is either partially or completely divided. The division into right and left ventricles enhances the separation of oxygen-rich and oxygen-poor blood. The more efficient circulatory and respiratory systems of reptiles are critical for animals with a keratinized epidermis.

Like fishes and amphibians, many extant reptiles lack metabolic mechanisms for regulating body temperature. They are **ectotherms**, meaning that their body temperature fluctuates with the temperature of the surrounding environment. Some reptiles have behavioral adaptations that help them maintain a body temperature higher than that of their environment (see Fig. 39-8a). For example, you may have observed a lizard basking in the sun, which raises its body temperature and so increases its metabolic rate. This increased rate permits the lizard to hunt actively for food. When the body of a reptile is cold, its metabolic rate is low and the animal tends to be sluggish. Ectothermy helps explain why lizards, snakes, and turtles are more successful in warm than in cold climates.

Many reptiles are predators. Their paired limbs, usually with five toes, are well adapted for running and climbing in search of prey. In addition, their well-developed sense organs enable them to locate prey.

Key Point

The diapsid reptiles gave rise to the birds, and the synapsids gave rise to the mammals. Note the five main branches of extant diapsids.

Figure 32-20 Evolutionary relationships of some amniotes

This cladogram shows proposed evolutionary relationships among reptiles, birds, and mammals. Systematists continue to study these relationships and may reinterpret some of them. Identify five main branches of extant diapsids on the cladogram. (Hint: Recall that turtles are diapsids even though they have “lost” their temporal openings during their evolution.)

CONNECT Are birds more closely related to extinct branches of reptiles or to mammals?

Biologists assign reptiles to two major lineages

The first major lineage, the **lepidosaurs**, includes squamates—snakes, lizards, worm lizards—and sphenodonts—tuataras, lizardlike animals that live in burrows (see Table 32-3). The second major lineage, **archosaurs**, includes the extant turtles, terrapins, and tortoises (testudines) and the crocodilians—crocodiles, alligators, caimans, and gavials. These animals, along with the birds, are the surviving reptiles of the archosaur lineage (FIG. 32-21).

The archosaur lineage also gave rise to three groups of animals that became extinct: (1) **pterosaurs**, flying reptiles of the Mesozoic era; (2) saurichians, a group of dinosaurs, including (*Tyrannosaurus*) that dominated the Mesozoic era; and (3)

ornithischians, another group of Mesozoic dinosaurs that included (*Triceratops*). Birds (*Aves*) descended from the saurichian lineage.

Lizards and snakes are common modern reptiles

Lizards and snakes are assigned to the squamate (squa-mate') clade. These animals have rows of scales that overlap like shingles on a roof, forming a continuous, flexible armor that is shed periodically. Lizards range in size from certain geckos, which weigh as little as 1 g (less than 0.1 oz), to the Komodo dragon of Indonesia, which may weigh 100 kg (220 lb). Their body sizes and shapes vary greatly. Some lizards—for example, the “worm lizards” and the glass lizards—are legless. Iguanas make up a genus of herbivorous lizards, ranging in size from 1.5 to 1.8 m (5 to 6 ft).

Table 32-3 Some Major Groups of Amniotes

Clades	Important Characters
DIAPSIDS	Skull with two pairs of temporal openings
LEPIDOSAURS Squamates Snakes, lizards, worm lizards  Sphenodonts Tuataras	Overlapping scales; a very successful group of modern reptiles Flexible armor of overlapping, horny scales, which are shed Snakes: elongated body with no limbs; flexible, loosely jointed jaw; protrusible forked tongue Lizards: slender body, typically with four legs; some with no legs Vertebrae concave at both ends; only two extant species
ICHTHYOSAURS (extinct) Marine reptiles of Mesozoic era 	Body shaped like that of modern dolphins; large eyes; vertical tail
ARCHOSAURS Testudines Turtles, terrapins, tortoises  Crocodylians Crocodiles, alligators, caimans, gavials  Pterosaurs (extinct) Flying reptiles of Mesozoic era  Saurischians (extinct) Mesozoic dinosaurs (<i>Tyrannosaurus</i> , <i>Diplodocus</i>)  Birds descended from this lineage. Ornithischians (extinct) Mesozoic dinosaurs (<i>Triceratops</i>) 	Mainly terrestrial; some specialized for flight; ventricle completely divided in extant forms Enclosed in bony shell; beak of keratin instead of teeth; some can withdraw head and legs into shell; temporal openings "lost" during their evolution ("anapsids") Heart with two atria and two ventricles; closest extant relative to birds Membranous wings Some were two-legged carnivores; others were four-legged herbivores; some had feathers Bipedal and quadrupedal herbivores; social behavior and parental care in many
SYNAPSIDS	Skull with one pair of temporal openings
Therapsids (extinct) Mammals descended from this lineage. 	Many mammal-like characters; became dominant land animals during Middle Permian period

Snakes are characterized by a flexible, loosely jointed jaw structure that allows them to swallow animals larger than the diameter of their own jaws. These reptiles have elongated bodies with no legs, although pythons have vestigial hind-limb bones (see Fig. 18-17). Remember that although not all the tetrapods have four limbs, all evolved from four-limbed ancestors. Snake eyes are covered by a transparent scale. They do not have movable eyelids. Also absent are an external ear opening, a tympanic membrane (eardrum), and a middle-ear cavity.

Snakes use their forked tongues as accessory sensory organs for touch and smell. Chemicals from the ground or air adhere to the tongue. Snakes rub the tips of their tongues across the opening of a sense organ in the roof of the mouth that detects odors.

Pit vipers and some boas also have *pit organs* that detect heat from endothermic prey (see Fig. 43-3). These snakes use their *pit organs* to locate and capture birds and small nocturnal mammals.

Some snakes, such as king snakes, pythons, and boa constrictors, kill their prey by rapidly wrapping themselves around the animal and squeezing so it cannot breathe. Others have fangs, which are hollow teeth connected to venom glands. When the snake bites, it pumps venom through the fangs into the prey. Some snake venoms cause the breakdown of red blood cells; others, such as that of the coral snake, are neurotoxins, which interfere with nerve function. Venomous snakes of the United States include rattlesnakes, copperheads, cottonmouths, and coral snakes. Except for the coral snakes, all are pit vipers.

Carlyn Iverson

(a) Green turtle (*Chelonia mydas*). The paddlelike appendages are adapted for swimming.

Pete Oxford/Minden Pictures

(b) The emerald tree boa (*Corallus canina*). This boa inhabits tropical South American forests. It rarely leaves the trees to go to the ground. Emerald boas use their heat-sensitive pit organs to locate prey.

Betty and Nathan Cohen/Visuals Unlimited

(c) Tuatara (*Sphenodon punctatus*). These nocturnal predators reach a length of 60 cm (more than 2 ft) or longer. There are two species of tuataras. Both are classified as endangered.

Figure 32-21 Representative extant reptiles

Worm lizards are considered modified lizards. They are well adapted for their burrowing lifestyle. They have elongated bodies with either no legs or a single pair of legs. In many species the eyes are hidden under the skin. Most are less than 15 cm (6 in.) long. Most species of worm lizards inhabit South America and southern Africa. Only one species (known as the Florida worm lizard) is found in the United States.

Trevor Kelly/Shutterstock.com

(d) Nile crocodiles (*Crocodylus niloticus*) hatching from their eggs. Both parents guard the leathery eggs. When the hatchlings emerge, the mother leads them to the water. She may carry them in her mouth.

Charles Martin

(e) Roseate spoonbill (*Ajaja ajaja*). The roseate spoonbill is a long-legged wading bird nearly three feet tall with a wingspan of more than four feet. This bird was photographed in John Prince Park, Lake Worth, Florida. The future of roseate spoonbills depends on protection of their habitats—coastal marshes, estuaries, and mangrove areas.

Tuataras superficially resemble lizards

Tuataras look somewhat like iguanas but have certain distinct characters. For example, they are the only amniotes with vertebrae that are concave at both ends; such vertebrae are characteristic of fish and some amphibians. The two extant species of tuataras inhabit New Zealand and several small islands off its coast. Tuataras have long been considered endangered species. When humans brought rats, cats, and dogs to New Zealand, these nonnative animals decimated the population of tuataras by eating their eggs. Tuataras became extinct on the New Zealand mainland. In 2005, these animals were reintroduced into a sanctuary in New Zealand, and they are now protected.

Turtles have protective shells

Turtles, terrapins, and tortoises are testudines (te-stood'-nee-z). They are enclosed in a protective shell made of bony plates overlaid by keratin scales. Some terrestrial turtles can

withdraw their heads and legs completely into their shells. Their keratin beak covers the jaws. They do not have teeth. Turtles are diapsid reptiles. During the course of evolution, members of this group have “lost” the temporal openings.

The size of adult turtles ranges in length from about 8 cm (3 in.) to more than 2 m (6.5 ft) in leatherback turtles, which are the largest marine species. The weight of a leatherback turtle can exceed 500 kg (more than 1000 lb). The forelimbs of marine turtles are modified into flippers. Sea turtles migrate hundreds of miles from the beaches where they hatch to feeding grounds. Females return to the same beaches where they hatched to mate and nest. Most species of sea turtles are endangered as a result of human activities.

Crocodylians have an elongated skull

Modern crocodylians include three groups: (1) the crocodiles of Africa, Asia, and the Americas; (2) the alligators of the southern United States and China, plus the caimans of Central America; and (3) the gavials of South Asia. Most species live in swamps, in rivers, or along seacoasts, feeding on various kinds of animals.

Crocodiles are the largest living reptiles; some exceed 7 m (23 ft) in length. The cranial skeleton is adapted for aquatic life. In the Americas, crocodiles can be distinguished from alligators or caimans by their more tapered snouts and by the large fourth tooth on the lower jaw that is visible when the mouth is closed.

How do we know that birds are really dinosaurs?

Cladistic analyses indicate that birds evolved from the lineage of saurischian dinosaurs, specifically from the **theropods** (their'-uh-pods), a group of bipedal, saurischian dinosaurs that included *Tyrannosaurus* and *Deinonychus* (see Fig. 21-15). This view is supported by the remarkable array of Cretaceous and late Jurassic fossils discovered in the Yixian Formation and in other parts of China as well as in Europe.

Some dinosaurs had feathers Paleontologists have identified many theropod dinosaur fossils that demonstrate the evolution of feathers from very simple, tubular structures to complex modern forms. *Caudipteryx*, a feathered dinosaur discovered in the Yixian Formation, was about the size of a turkey. Fossils of *Caudipteryx* exhibit both dinosaur and bird characteristics. The bones in the foot and the shape and orientation of the pelvis were similar to those of dinosaurs. However, the fossils have well-preserved impressions of complex feathers on the tail and forelimbs. *Caudipteryx* had only a few teeth in the front of its upper jaw, and its bones show many birdlike characteristics. Although some investigators have argued that *Caudipteryx* was a flightless bird, the most recent consensus view is that this animal was a feathered dinosaur. Analyzing fossil evidence and molecular data, many

paleontologists have hypothesized that feather evolution took place in terrestrial, bipedal dinosaurs *before* the evolution of birds or flight.

Asymmetrical feathers were important in the evolution of flight. Modern birds have asymmetrical feathers. In 2003, paleontologists reported finding a new species of feathered dinosaur, *Microraptor gui*. *Microraptor* had asymmetrical feathers on both its forelimbs and hind limbs, and also on its tail. (See the figure in *Inquiring About: The Origin of Flight in Birds* in Chapter 21.) However, their small size and body structure support the hypothesis that flying evolved from gliding; that is, *Microraptor* climbed trees and used its feathered limbs for gliding. These small dinosaurs, which lived about 126 mya, coexisted with early birds.

Biologists have debated why feathers may have evolved in dinosaurs. Were feathers important in courtship rituals or in camouflage? Were feathers an adaptation that conserved body heat? Insulating feathers could have contributed to the evolution of endothermy (the ability to maintain a constant body temperature), permitting animals to be more active.

Scientists have discovered fossils of more than 30 species of feathered dinosaurs. In 2010, paleontologists described a nearly complete skeleton of a basal theropod discovered in northwestern China. This fossil, named *Haplocheirus sollers*, had organelles containing pigment that colored its feathers, suggesting that feathers may have first evolved for color displays in courtship rituals. The presence of feathers and the bone structure of *Haplocheirus* indicate that striking evolutionary convergence occurred between feathered dinosaurs and birds. In 2016, scientists discovered the fossil of a birdlike dinosaur in Liaoning, China. Named *Jianianhualong tengi*, this dinosaur lived about 125 mya. It looked somewhat like a chicken with asymmetrical feathers that were longer on one side. The feathers had stiff quills with barbs.

Early birds were transitional forms

Many extinct theropods were long-tailed animals that moved about on two feet and had forelimbs with three clawed fingers. Although the bones of birds are fragile and disintegrate quickly, paleobiologists have found a few fossils of early birds. The first birds looked very much like dinosaurs. They had teeth (which modern birds lack), a long tail, and bones with thick walls. Like certain extinct theropods, modern birds have feet with three digits and thin-walled, hollow bones. Both have a *furcula*, or wishbone, which is formed by the two clavicles (collarbones) fusing in the midline. Many biologists classify modern birds as theropods.

Archaeopteryx (meaning “ancient wing”) was an early bird that was about the size of a pigeon. More than ten specimens of this genus have been found in Bavaria in Jurassic limestone, which was laid down about 150 mya. Unlike those of extant birds, the jawbones of *Archaeopteryx* were armed with teeth, and its long, reptilian tail was covered with feathers (FIG. 32-22a). Each of its short, broad wings had three claw-bearing, functional digits.

(a) **Reconstruction of *Archaeopteryx*, an early bird.** This reconstruction illustrates a feathered *Archaeopteryx* preying on a dragonfly. *Archaeopteryx* was a climbing animal that had at least some ability to use its wings and feathers for gliding.

(b) **Fossil of *Aurornis xui*, a very early bird.** *Aurornis xui*, about the size of a pheasant, lived during the Middle–Late Jurassic period about 160 million years ago.

Figure 32-22 Fossil evidence supports the evolution of birds from the dinosaur lineage

Like modern birds, *Archaeopteryx* had wings, feathers, and a furcula. Its feathers were very similar to those of modern birds.

Using computer tomography and computerized 3-D reconstruction, researchers examined the inside of the *Archaeopteryx* skull. They found that *Archaeopteryx* had a birdlike brain with comparatively larger cerebral lobes than those of other reptiles. It had enlarged visual centers and highly developed inner ear canals similar to those of modern birds. These structures would support the coordination and agility needed for flight.

A complete fossil of an early bird from China was described in 2013. This fossil, named *Aurornis xui*, predates *Archaeopteryx* by about 10 million years. Like *Archaeopteryx*, *Aurornis xui* has a furcula, feathers, and teeth (FIG. 32-22b). The *Aurornis* fossil preserved traces of downy feathers. However, it shows no evidence of larger feathers, suggesting that this early bird was not able to fly.

Cretaceous rocks have yielded fossils of other early birds. *Hesperornis*, which lived in North America, was a toothed,

aquatic diving bird with small wings and broad, lobed feet for swimming. *Ichthyornis* was a toothed, flying bird about the size of a small tern. Based on fossils, structural similarities, and molecular data, most biologists now view birds as living dinosaurs.

Modern birds are adapted for flight

By the end of the Cretaceous period, the major clades of present-day birds—palaeognaths and neognaths—had evolved. (Some biologists assign birds to class Aves and consider palaeognathae and neognathae as superorders.) *Palaeognaths* (from Greek *palaios*, “ancient,” and *gnathos*, “jaw”) include flightless birds such as the ostrich, kiwi, cassowary, and emu. These birds are called **ratites**. Their sternum (breastbone) is flat and does not have a ridge for attachment of wing muscles. They have only vestigial wings, but they have well-developed legs used for running.

Most modern birds are *neognaths* (from Greek *neos*, “new,” and *gnathos*, “jaw”). These birds have powerful flight muscles attached to their keeled (ridged) sternum, and most neognaths fly. The penguins are an exception. They use their strong pectoral muscles and small, flipperlike wings to swim.

Biologists have described more than 10,000 species of extant birds and classified them into about 23 monophyletic taxa. Birds are a diverse group (FIG. 32-23). They have become adapted to a variety of environments, and various species have different types of beaks, feet, wings, tails, and behavioral patterns. They can be found on all continents, most islands, and even the open sea. The largest living birds are the ostriches of Africa, which may be up to 2 m (6.5 ft) tall and weigh 136 kg (300 lb). The great condors of the Americas have wingspans of up to 3 m (10 ft). The smallest known bird is the bee hummingbird of Cuba, with a length of less than 6 cm (about 2 in.) and a weight of less than 2 g (about 0.06 oz).

Like their reptilian ancestors, modern birds lay eggs and have reptilian-type scales on their legs. Birds have evolved remarkable specializations for flight. They are the only extant animals with feathers. Their feathers are an amazing example of biological engineering. They are very light, yet flexible and strong, and present a flat surface to the air. Feathers also protect the body and decrease water and heat loss. The anterior limbs of birds are wings, usually adapted for flight. The posterior limbs are modified for walking, swimming, or perching.

Other adaptations for flight include the compact, streamlined body and the fusion of many bones, which provides the rigidity needed for flying. The bones are strong but very light. Many are hollow, containing large air spaces. The avian jaw is light, and instead of teeth, birds have a lightweight beak of bone and keratin. The breastbone is broad and keeled for the attachment of the large flight muscles.

Birds have lungs with *air sacs*, thin-walled extensions that occupy spaces between the internal organs and within certain bones. The unique “one-way” flow of air through their respiratory system is metabolically efficient because their lungs

(c) Atlantic puffin (*Fratercula arctica*). This puffin has caught several fish. The puffin's beak becomes brightly colored during the breeding season.

Figure 32-23 Modern birds

Although they are diverse, most birds are highly adapted for flight, and their basic structure is similar.

can extract great amounts of oxygen from the air. (This respiratory system is described in more detail in Chapter 46.)

Birds have a four-chambered heart and a double circuit of blood flow. One circuit delivers oxygen-rich blood to the body tissues and returns low-oxygen blood to the heart; the other circuit takes blood to and from the lungs where it is oxygenated. The very effective respiratory and circulatory systems provide the cells with enough oxygen to permit a high metabolic rate, which is necessary for the strenuous muscular activity that flying requires. Some of the heat a bird generates by metabolic activities helps it maintain a constant body temperature. Because they are endotherms, birds can remain active in cold climates.

Birds excrete nitrogenous wastes mainly as semisolid uric acid. Because birds typically do not have a urinary bladder, these solid wastes are delivered into the cloaca. They leave the body with the feces, which are dropped frequently. This adaptive mechanism helps maintain a light body weight.

Bills are specifically adapted for the type of food the bird eats (see Fig. 1-13). Birds must eat frequently because they have a high metabolic rate and typically do not store much fat. Although the choice of food varies widely among species, most birds eat energy-rich foods such as seeds, fruits, worms, mollusks, or arthropods. Warblers and some other species eat mainly insects. Owls and hawks eat small mammals and

other birds. Some hawks catch snakes and lizards. Vultures feed on dead animals. Pelicans, gulls, terns, and kingfishers catch fish.

An interesting feature of the bird digestive system is the *crop*, an expanded, saclike portion of the digestive tract below the esophagus in which food is temporarily stored. The stomach is divided into a *proventriculus*, which secretes gastric juices; and a thick, muscular *gizzard*, which grinds food. The bird swallows small bits of gravel that act as “teeth” in the gizzard to mechanically break down food.

Birds have a well-developed nervous system, with a brain that is proportionately larger than that of other reptiles. Birds rely heavily on vision, and their eyes are relatively larger than those of other vertebrates. Hearing is also well developed.

In striking contrast with the relatively silent non-avian reptiles, birds are very vocal. Most have short, simple *calls* that signal danger or influence feeding, flocking, or interaction between parent and young. *Songs* are usually more complex than calls and are performed mainly by males. Birds sing songs to attract and keep a mate and to claim and defend a territory.

One of the most fascinating aspects of bird behavior is the annual migration made by many species. Some birds, such as the golden plover and Arctic tern, fly from Alaska to Patagonia, South America, and back each year, covering perhaps 40,250 km (25,000 mi) en route. Migration and navigation are discussed in Chapter 52.

Many birds have beautiful, striking colors. The colors are due partly to pigments deposited during the development of the feathers and partly to reflection and refraction of light of certain wavelengths. Many birds, especially females, are protectively colored by their plumage. During the breeding season, the male often assumes brighter colors, which help attract a mate.

Mammals (class Mammalia) have many unique characters

Derived characters include **mammary glands** that produce milk for the young; hair (all **mammals** have at least a few hairs at some time in their life, and no other organism has true hair); one pair of temporal openings in the skull; differentiated **teeth** (incisors, canines, premolars, and molars); lungs with alveoli; completely divided ventricles; **kidneys**, which help conserve water; and three **middle-ear bones** (other tetrapods have only a single bone, the stapes, in the middle ear). The evolution of the **cochlea**, the organ of hearing in the inner ear, gives mammals an excellent sense of hearing.

Contributing significantly to the success of the mammals, *the nervous system is more highly developed than in any other group of animals*. The cerebrum is especially large and complex, with an outer gray region, the **cerebral cortex**. In mammals the highly specialized cerebral cortex, called the **neocortex**, has six layers of neurons. Specific regions in the neocortex are specialized for functions such as vision, hearing, touch, movement, emotional response, and higher cognitive functions.

Fertilization in mammals is internal, and with the exception of the monotremes that lay eggs, mammals are viviparous. Most mammals develop a **placenta**, an organ of exchange between developing embryo and mother. As the mother's blood passes through blood vessels in the placenta, it delivers nourishment and oxygen to the embryo and carries off wastes. By carrying their developing young internally, mammals avoid the hazards of having their eggs consumed by predators. By nourishing the young and caring for them, the parents offer both protection and an "education" on how to obtain food and avoid being eaten.

A muscular **diaphragm** helps move air into and out of the lungs. Like birds, mammals are endotherms, but mammals appear to have evolved endothermy independently of birds. Some of the adaptations that allow mammals to maintain a constant body temperature include the covering of insulating hair, very efficient lungs with alveoli (air sacs through which gas exchange with the blood takes place), a fully divided ventricle, and complete separation of pulmonary and systemic circulations. Red blood cells without nuclei serve as efficient oxygen transporters.

The limbs of mammals are variously adapted for walking, running, climbing, swimming, burrowing, or flying. In most terrestrial mammals, the limbs are more directly under the body than they are in extant reptiles, which contributes to speed and agility.

New fossil discoveries are changing our understanding of the early evolution of mammals

Mammals descended from **therapsids**, a group of synapsid amniotes, during the Triassic period more than 200 mya. The therapsids were somewhat doglike carnivores with differentiated teeth and legs adapted for running (FIG. 32-24). Until recently, early mammals were thought to be small, about the size of a mouse or shrew. However, fossil evidence indicates that mammals diversified earlier than previously thought. Some early mammals were fairly large, with limbs adapted for swimming or burrowing. Some had fur, and some were probably endothermic.

How did mammals manage to coexist with the abundant archosaurs during the approximately 160 million years that reptiles ruled Earth? Many adaptations permitted early mammals to compete for a place on this planet. Perhaps one of the most important was their skill at being inconspicuous. Many were **arboreal** (tree dwelling) and nocturnal (active at night), searching for food (mainly insects and plant material, and perhaps reptile eggs) at night while the reptiles were inactive. Although their eyes may have been small, early mammals had well-developed sense organs for hearing and smell.

As many reptiles became extinct, mammals adapted to the niches (lifestyles) that reptiles abandoned. During this time, the flowering plants, including many trees, underwent an adaptive radiation, providing new habitats, sources of food, and protection from predators. Numerous new varieties of mammals evolved. During the Early Cenozoic era (more than 55 mya), the mammals underwent an adaptive radiation; they became widely distributed and adapted to an impressive variety of ecological lifestyles.

Figure 32-24 Therapsid (*Lycaenops*)

The therapsids were synapsid amniotes. *Lycaenops*, a predator about the size of a coyote, lived in South Africa during the Late Permian period.

Figure 32-25 Evolution of mammals
This cladogram shows the current interpretation of the evolution of mammals.

Modern mammals are assigned to three subclasses

By the end of the Cretaceous period, three main lineages of mammals had evolved (FIG. 32-25). Mammals now inhabit virtually every corner of Earth; they live on land, in fresh water and salt water, and in the air. They range in size from the tiny pygmy shrew, weighing about 2.5 g (less than 0.1 oz), to the blue whale, which may weigh up to 136,000 kg (150 tons) and which is probably one of the largest animals that has ever lived.

Modern mammals are classified in two main clades: **protheria**, which includes the **monotremes**, egg-laying mammals; and **theria**, which includes the mammals that bear their young alive. The therian clade is further divided into two groups: Metatheria, the **marsupials** (pouched mammals); and Eutheria, mammals that are more developed at birth than the marsupials. **Eutherians** are often referred to as placental mammals because they have well-developed placentas. However, some marsupials do have simple placentas.

One group of protherians includes the duck-billed platypus and a second, the spiny echidnas (FIG. 32-26). These animals live in Australia and Tasmania; two species of spiny echidnas inhabit New Guinea. Female protherians lay eggs that they carry in a pouch on the abdomen or keep warm

Figure 32-26 Short-beaked echidna (*Tachyglossus aculeatus*)

Female protherians lay eggs. They have mammary glands, but do not have nipples.

in a nest. When the young hatch, they lap up milk secreted by their mother's mammary glands. Unlike other mammals, monotremes do not have nipples. With their long beaks and long, sticky tongues, spiny echidnas capture ants and termites. The duck-billed platypus, which lives in burrows along river banks, preys on freshwater invertebrates. It has webbed feet and a flat, beaverlike tail, which help it swim.

Marsupials include pouched mammals such as kangaroos and opossums (FIG. 32-27a). Embryos begin their development in the mother's uterus, where they are nourished by fluid and yolk. After a brief gestation, the young are born in an undeveloped stage. The young make their way to the *marsupium* (pouch), where they attach to a nipple. Nourished by the mother's milk, they complete their development (FIG. 32-27b).

At one time, marsupials probably inhabited much of the world, but placental mammals largely outcompeted them. Now marsupials live mainly in Australia, Central America, and South America. The only marsupial species that ranges into the United States is the Virginia opossum. Australia became geographically isolated from the rest of the world before placental mammals migrated there, and the marsupials remained the dominant mammals (see the discussion of continental drift in Chapter 18). Australian marsupials underwent adaptive radiation, paralleling the evolution of placental mammals elsewhere. Thus, marsupials that live in Australia and adjacent islands independently evolved body forms and natural histories similar to North American placental wolves, bears, rats, moles, flying squirrels, and even cats (FIG. 32-28).

Most familiar to us are the eutherian mammals, which are born at a more mature stage than marsupials (FIG. 32-29). Indeed, among some species the young can walk and begin to interact with other members of the group within a few minutes after birth. Eutherians have a well-developed placenta. The placenta

SeaWorld Parks & Entertainment

(b) A kangaroo soon after birth. Marsupials are born in an embryonic state and continue to develop in the safety of the mother's marsupium (pouch).

Figure 32-27 Marsupials

develops from both embryonic membranes and the maternal uterine wall. In the placenta, blood vessels of the embryo come very close to the blood vessels of the mother, so materials can be exchanged by diffusion. (The two circulations do not normally mix.) The placenta allows the young to remain within the mother's body until embryonic development is complete.

Extant placental mammals can be assigned to about 19 groups (orders). **TABLE 32-4** gives a brief summary of some of these groups. Remember that aquatic mammals, such as dolphins, whales, and seals, evolved from terrestrial ancestors (see Fig. 18-9). Also refer to **TABLE 32-5**, which reviews the three main deuterostome groups.

Figure 32-28 Convergent evolution in eutherian and marsupial mammals

For each mammal in one group, a counterpart has evolved in the other group. Their similarities include both lifestyles and structural features.

✓ CHECKPOINT 32.8

- **CONNECT** Describe three adaptations that have allowed amniotes to become completely terrestrial.
- **CONNECT** Which amniotes are endothermic? What are some advantages of endothermy?
- Argue for classifying birds and reptiles in a single clade.
- Contrast the three main clades of mammals.

McMurray Photography

(a) Wildebeest (*Connochaetes taurinus*), photographed in Tanzania. The dominant plains antelope in many areas of eastern and southern Africa, wildebeest migrate long distances during the dry season in search of food and water.

Hyde John/Getty Images

(b) Humpback whales (*Megaptera novaeangliae*) exhibiting a rare double breach.

Jamen Percy/Shutterstock.com

(c) Wolverine (*Gulo gulo*), a tough, powerful animal. Wolverines are fierce predators that sometimes take down large prey, such as caribou. The wolverine population has declined due to trapping, fragmentation of their habitat, and reduction of their range. Their habitat is also being reduced by climate change. They are protected by the Endangered Species Act.

Arco Images GmbH/Alamy Stock Photo

(d) Egyptian fruit bat (*Rousettus aegyptiacus*). Often called “flying foxes,” these small bats cluster in large colonies. They often hang by one foot from the cave ceiling.

Figure 32-29 Eutherian mammals

Table 32-4 Some Groups (Orders) of Extant Eutherian Mammals

Order, Representative Members, and Some Characteristics

INSECTIVORA (moles, hedgehogs, shrews)
Nocturnal; eat insects. Shrew is smallest living mammal; some weigh less than 5 g (about 0.2 ounces).

African hedgehog
Atelerix albiventris

CHIROPTERA (bats)

Adapted for flying; fold of skin extends from elongated fingers to body and legs, forming wing. Guided in flight by type of biological sonar; emit high-frequency squeaks and are guided by echoes from obstructions. Eat insects and fruit or suck blood of other animals.

Bat
Eptesicus fuscus

ARTIODACTYLA (cattle, sheep, pigs, deer, giraffes)

Hoofed with even numbers of digits per foot; most have two toes, some have four. Most have antlers or horns. Herbivores; most are ruminants, chew a cud, and have a series of stomachs inhabited by bacteria that digest cellulose.

American elk
Cervus elaphus

XENARTHRA (sloths, anteaters, armadillos)

Teeth reduced or no teeth. Sloths are sluggish animals that hang upside down from branches; often protectively colored by green algae that grow on their hair. Armadillos are protected by bony plates; eat insects and small invertebrates.

Nine-banded armadillo
Dasypus bellus

Continued

Table 32-4 Some Groups (Orders) of Extant Eutherian Mammals (*continued*)

Order, Representative Members, and Some Characteristics

CARNIVORA (cats, dogs, wolves, foxes, bears, otters, mink, weasels, skunks, seals, sea lions, walruses)

Predators with sharp, pointed canine teeth and molars for shearing; keen sense of smell; complex social interactions; among fastest, strongest, and smartest animals. Seals, sea lions, and walruses are large marine predators with limbs adapted as flippers for swimming.

Wolf
Canis lupus

PERISSODACTYLA (horses, zebras, tapirs, rhinoceroses)

Herbivores; hoofed with odd number of digits per foot; one or three toes; teeth adapted for chewing; usually large animals with long legs.

Tapir
Tapirus sp.

LAGOMORPHA (rabbits, hares, pikas)

Like rodents, have chisel-like incisors; typically have long hind legs adapted for jumping; many have long ears.

Pika
Ochotona sp.

PRIMATES (lemurs, monkeys, apes, humans)

Highly developed brain and eyes; nails instead of claws; opposable thumb; eyes directed forward; omnivores; most species arboreal. (Primate evolution is discussed in Chapter 22.)

Ring-tailed lemur
Lemur catta

RODENTIA (squirrels, beavers, rats, mice, hamsters, porcupines, guinea pigs)

Gnawing animals with chisel-like incisors. As they gnaw, teeth are worn down and so must grow continually. Most numerous mammals both in numbers and species.

Flying squirrel
Glaucomys volans

PROBOSCIDEA (elephants)

Largest land animals; weigh up to 7 tons; large head; broad ears; long, muscular, flexible trunk (proboscis); thick loose skin is characteristic; two upper incisors are elongated as tusks. Includes extinct mastodons and woolly mammoths.

African elephant
Loxodonta africana

SIRENIA (sea cows, manatees)

Herbivorous, aquatic mammals with finlike forelimbs and no hind limbs. They are probably the basis for most tales about mermaids. Evolved from Proboscidean ancestors.

Manatee
Trichechus manatus

CETACEA (whales, dolphins, porpoises)

Adapted for aquatic life with fish-shaped body and broad, paddlelike forelimbs (flippers); posterior limbs absent; many have thick layer of blubber under skin; some are filter feeders; mate and bear young in the water; very intelligent. Evolved from Artiodactyl ancestors.

Humpback whale
Megaptera novaeangliae

Table 32-5 Overview of the Deuterostomes

Major Groups		Body Plan	Key Characteristics
Echinoderms (sea stars, sea urchins, sand dollars)		Larva bilateral, ciliated; adult pentaradial; triploblastic; organ systems; complete digestive tube	Endoskeleton with spines; water vascular system functions in locomotion, feeding, and gas exchange; tube feet; marine
Hemichordates (acorn worms)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Ring of cilia surrounds mouth; three-part body: proboscis, collar, and trunk; pharyngeal slits; wormlike marine animals
Chordates (tunicates, lancelets, vertebrates)		Bilateral symmetry; triploblastic; organ systems; complete digestive tube	Notochord; dorsal, tubular nerve cord; endostyle; postanal tail; pharyngeal slits during some time in life cycle; segmented muscles

Summary: Focus on Learning Objectives

32.1 What Are Deuterostomes? (page 677)

1 Identify shared derived characters of deuterostomes and briefly describe the hemichordates.

- The **deuterostomes** include echinoderms, hemichordates, and chordates. Shared derived characters include: radial, indeterminate cleavage; the blastopore becomes (or is near the future site of) the anus; and pharyngeal slits at some time in the life cycle. Basal deuterostomes have a larva with a loop-shaped ciliated band used for locomotion.
- Hemichordates** (acorn worms) are marine deuterostomes with a three-part body, including proboscis, collar, and trunk.

32.2 Echinoderms (page 677)

2 Identify three shared derived characters of echinoderms and describe the main clades (classes) of echinoderms.

- Echinoderms** (*Echinodermata*) are marine animals with a spiny “skin,” **water vascular system**, **tube feet**, and **endoskeleton**. The larvae exhibit bilateral symmetry; most of the adults exhibit *pentaradial symmetry*.
- Clade Crinoidea includes sea lilies and feather stars. The *oral surface* of crinoids is turned upward; some crinoids are sessile.
- Clade Asteroidea consists of the sea stars. They have a central disc with five or more arms, and they use tube feet for locomotion.
- Clade Ophiuroidea includes the brittle stars, which resemble sea stars but have longer, more slender arms that are set off more distinctly from the central disc. They use their arms for locomotion. Their tube feet lack suckers and are not used in locomotion.
- Clade Echinoidea includes the sea urchins and sand dollars. Echinoids lack arms; they have a solid shell and are covered with spines.
- Clade Holothuroidea consists of sea cucumbers, animals with elongated flexible bodies. The mouth is surrounded by a circle of modified tube feet that serve as tentacles.

32.3 The Chordates: Major Characteristics (page 681)

3 Describe characteristics of chordates, including four shared derived characters.

- The **chordates** include three groups: tunicates (Urochordata), lancelets (Cephalochordata), and vertebrates (Vertebrata). At some time in its life cycle, a chordate has a flexible, supporting **notochord**; a **dorsal, tubular nerve cord**; a muscular **postanal tail**; and an **endostyle**, or thyroid gland; they are also characterized by **pharyngeal slits**, but that is a derived character of deuterostomes.

32.4 Invertebrate Chordates (page 682)

4 Compare tunicates and lancelets, and summarize the phylogeny of chordates.

- The **tunicates** are **urochordates**, suspension-feeding marine animals with tunics. Larvae have typical chordate characteristics and are free-swimming. Adults of most groups are sessile suspension feeders.

- The *lancelets* are **cephalochordates**, small, segmented, fishlike animals; their chordate characteristics are highly developed.
- The available evidence suggests that urochordates are the sister group of the vertebrates.

32.5 Introducing the Vertebrates (page 684)

5 Describe four shared derived characters of vertebrates.

- The vertebrates have a *vertebral column* composed of *vertebrae* that forms the chief skeletal axis of the body and a braincase, or **cranium**. **Neural crest cells** are embryonic cells important in the development of many structures, including the cranium and jaws. Vertebrates have pronounced cephalization and 10 or 12 pairs of cranial nerves. They have a complex brain, a muscular pharynx, and muscles attached to the endoskeleton.

6 Describe the major taxa of extant vertebrates.

- Vertebrates can be assigned to 10 clades (formerly referred to as classes). The hagfishes, which make up the *Myxini*, and the lampreys, which make up the *Petromyzontida*, have neither jaws nor paired fins. The *Chondrichthyes* comprise the sharks, rays, and skates; they are jawed fishes with skeletons of cartilage. The extant (living) bony fishes can be assigned to three clades (classes): *Actinopterygii*, ray-finned fishes; *Actinistia*, coelacanth; and *Dipnoi*, lungfishes.
- The **tetrapods** (Tetrapoda) include the amphibian clades (salamanders, frogs, and caecilians), many of which have aquatic larvae that undergo metamorphosis, and the amniote lineage (Amniota), which includes reptiles and mammals. **Reptiles** (clade Reptilia) include lizards, snakes, turtles, alligators, and birds.
- Reptiles are amniotes with keratin scales or feathers and reproduction adapted for terrestrial life; mammals (clade Mammalia) include monotremes, marsupials, and placental mammals. Mammals are amniotes with hair and mammary glands. (See Table 32-2 for a more detailed review.)

32.6 Jawless Fishes (page 686)

7 Distinguish among the major groups of jawless fishes.

- The extant jawless fishes are the hagfishes (*Myxini*) and the lampreys (*Petromyzontida*). Jaws and paired fins are absent in both hagfishes and lampreys. Hagfishes are marine scavengers that secrete slime as a defense mechanism. Many lampreys are parasites on other fishes.

32.7 Evolution of Jaws and Limbs: Jawed Fishes and Tetrapods (page 688)

8 Trace the evolution of jawed fishes and early tetrapods, and describe modern amphibians.

- Chondrichthyes, the cartilaginous fishes (sharks, rays, and skates), evolved during the Devonian period. They have jaws, two pairs of fins, and **placoid scales**.
- During the Devonian period, bony fishes gave rise to two evolutionary lines: the Actinopterygii, or **ray-finned fishes**, and the Sarcopterygii, or **lobe-finned fishes**. The ray-finned fishes gave rise to the modern bony fishes. Their lungs have been modified as a **swim bladder**, an air sac for regulating buoyancy.
- The Sarcopterygii includes the Tetrapodomorpha, the *lungfishes* (Dipnoi), and the **coelacanth**s (Actinistia). Evidence suggests that the Tetrapodomorpha gave rise to the **tetrapods**, the land vertebrates. *Tiktaalik* was a transitional form between fishes and tetrapods.
- Early tetrapods were mainly aquatic animals that ventured onto the land to find food or escape predators. These early tetrapods had limbs strong enough to support the weight of their bodies on land.
- Modern **amphibians** (Amphibia) include salamanders and newts, frogs and toads, and caecilians. Most amphibians return to the water to reproduce. Frog embryos develop into tadpoles, which undergo **metamorphosis** to become adults. Amphibians use their moist skin as well as lungs for gas exchange. They have systemic and pulmonary circulations as well as hearts with two atria and one ventricle.

32.8 Amniotes: Terrestrial Vertebrates (page 694)

9 Describe three vertebrate adaptations to terrestrial life.

- Terrestrial vertebrates, or **amniotes**, include reptiles (including birds) and mammals. Adaptations for life on land include (1) the evolution of the **amniotic egg** with its shell and **amnion**, a membrane that forms a fluid-filled sac around the embryo; (2) internal fertilization; and (3) a body covering that retards water loss and physiological mechanisms that conserve water.

10 Describe the reptiles (including the birds) and argue for including the birds in the reptile clade.

- Biologists classify amniotes in two main groups: diapsids and synapsids. **Diapsids** include the turtles, squamates (snakes and lizards), tuataras, extinct ichthyosaurs, crocodiles, the extinct pterosaurs, the extinct ornithischian dinosaurs, the extinct saurischian dinosaurs, and birds. The **synapsids** include the **therapsids**, which gave rise to the mammals. (See Table 32-3.)
- Extant **reptiles** (including birds) can be classified in five clades: (1) turtles, terrapins, and tortoises; (2) lizards, snakes, and worm lizards; (3) tuataras; (4) crocodiles, alligators, caimans, and gavials; and (5) birds (avian reptiles).
- Most non-avian reptiles have dry skin with horny scales, lungs with many chambers, and a heart with two completely separated atria and two ventricles that are incompletely separated. (In the crocodiles the two ventricles are completely partitioned.) Birds have many adaptations for powered flight, including feathers; wings; and light, hollow bones containing air spaces. They have completely divided ventricles and very efficient lungs, and they excrete solid metabolic wastes (uric acid). They are **endotherms**; that is, they maintain a constant body temperature. Birds have a well-developed nervous system with excellent vision and hearing.
- Based on fossil evidence and molecular data, feather evolution took place in terrestrial, bipedal dinosaurs before the evolution of birds or flight. Birds are considered feathered reptiles that evolved from the lineage of saurischian dinosaurs, specifically from the **theropods**, a group of bipedal, saurischian dinosaurs. Like theropods, modern birds have feet with three digits; thin-walled, hollow bones; and a *furcula*, or wishbone.

11 Describe five key characters of mammals and contrast protherian (monotremes), metatherian (marsupials), and eutherian mammals, giving examples of animals that belong to each group.

- **Mammals** have several derived characters, including **mammary glands**, hair, one pair of temporal openings in the skull, differentiated teeth, lungs with alveoli, completely divided ventricles, three middle-ear bones, and a highly developed nervous system, including a neocortex.
- Mammals can be assigned to two clades: **protherians** and **therians**. The protherians are the **monotremes**, mammals that lay eggs. This clade includes the duck-billed platypus and spiny anteaters.
- Therians bear their young alive. This clade includes metatheria (marsupials) and **eutherians**, mammals with a well-developed placenta. The **marsupials** are pouched mammals, such as kangaroos and opossums. The young, born at an immature stage, complete their development in their mother's marsupium, where they are nourished with milk from mammary glands.
- Eutherians are more developed at birth than marsupials; they are characterized by a well-developed **placenta**, an organ of exchange that develops between the embryo and the mother.

Test Your Understanding

Know and Comprehend

1. Which of the following is *not* a shared derived character of echinoderms? (a) water vascular system (b) notochord (c) tube feet (d) pentaradial symmetry in adult (e) endoskeleton of calcium carbonate plates and spines
2. Which of the following is/are found in tunicates? (a) dorsal, tubular nerve cord (b) tube feet (c) anal gill slits (d) two pairs of appendages (e) vertebral column
3. A shark is characterized by (a) amnion (b) bony skeleton (c) water vascular system (d) placoid scales (e) endothermy *and* amnion
4. Which of the following characteristics is/are associated with amphibians? (a) amnion (b) placoid scales (c) heart with two complete ventricles (d) swim bladder (e) metamorphosis
5. Reptiles (a) are all endotherms (b) are amniotes (c) have a great deal of keratin in their epidermis (d) have external fertilization (e) b and c are both correct
6. Which of the following is *not* characteristic of birds? (a) hollow bones (b) amnion (c) ectothermy (d) high metabolic rate (e) reptilian-like scales on legs
7. Which of the following is true of mammals? (a) they evolved from saurischian dinosaurs (b) they are exotherms (c) they have hair and three middle ear bones (d) mammalian embryos do not have an amnion (e) they all bear their young alive (do not lay eggs).

Apply and Analyze

8. **VISUALIZE** Draw a simple cladogram illustrating the evolutionary relationships among extant mammals (marsupials,

eutherians, and monotremes). Include the following characters in your cladogram: well-developed placenta, vivipary, endothermy, marsupium, hair.

9. **EVOLUTION LINK** Sea urchins have radial symmetry. Explain why they are *not* classified as cnidarians.
10. **EVOLUTION LINK** Most biologists consider birds as living dinosaurs. Justify this position.
11. **EVOLUTION LINK** Discuss the relationships among the echinoderms and chordates, describing shared derived characters that support grouping these animals as deuterostomes.

Evaluate and Synthesize

12. **INTERPRET DATA** Imagine that you discover an interesting new animal. You examine it and gather the following data. It has a dorsal, tubular nerve cord; a cranium; skin with scales; and a heart with two atria and two ventricles. How would you classify the animal? Explain each step in your decision. Where would you place this animal on the cladogram shown in Figure 32-20?
13. **SCIENCE, TECHNOLOGY, AND SOCIETY** Every year hundreds of sea turtles are injured and killed as a result of human activities. All seven species of marine turtles are listed under the Endangered Species Act. What measures would you propose to protect sea turtles?

33 Plant Structure, Growth, and Development

KEY CONCEPTS

- 33.1** The structure of plant cells, tissues, and organs matches their functions. The vascular plant body is differentiated into three tissue systems: the ground tissue system, the vascular tissue system, and the dermal tissue system.
- 33.2** Primary meristems lengthen roots and shoots throughout the lifespan of most plants. Woody plants have both primary meristems and secondary meristems, which increase roots and shoots in thickness.
- 33.3** Plant development requires not only cell division and expansion but also cell determination and cell differentiation, and pattern formation and morphogenesis.

PHOTO: Foxgloves, herbaceous biennials, and oxeye daisies, herbaceous perennials. Foxgloves (*Digitalis purpurea*) and oxeye daisies (*Leucanthemum vulgare*) grow wild in this mountain meadow in Idaho. These non-native species are also popular garden plants. Foxglove is the source of digitalis, which is used to treat heart disease. Lee O'Dell/Shutterstock.com

The more than 300,000 species of flowering plants that live in and are adapted to the many environments on Earth represent remarkable variety. From desert cacti with enormously swollen stems, to cattails partly submerged in marshes, to orchids growing in the uppermost tree branches of lush tropical rain forests, they are all recognizable as plants. Almost all plants have the same basic body plan, which consists of roots, stems, and leaves.

Plants are either herbaceous or woody. *Herbaceous* plants are nonwoody. In temperate climates, the aerial parts (stems and leaves) of herbaceous plants die back to the ground at the end of the growing season. In contrast, the aerial parts of *woody* plants (trees and shrubs) persist. Botanically speaking, woody plants produce hard, lignified secondary tissues (the cell walls of secondary tissues contain *lignin*), and herbaceous plants do not. Lignin and the production of secondary tissues are discussed later in this chapter and in Chapters 35 and 36.

Annual plants are herbaceous plants (such as corn, geraniums, and marigolds) that grow, reproduce, and die in one year or less. Other herbaceous plants (such as carrots, Queen Anne's lace, cabbages, and foxgloves) are **biennial plants**; they take two years to complete their life cycles before dying (see photograph). During their first season, biennials produce extra carbohydrates, which they store and use during their second year, when they typically form flowers and reproduce.

Perennial plants are herbaceous or woody plants that have the potential to live for more than two years. In temperate climates the aerial (aboveground) stems of herbaceous perennials such as irises, rhubarb, onions, asparagus, and oxeye daisies (see photograph) die back each winter. Their underground parts (roots and underground stems) become dormant during the winter and send out new growth each spring. (In **dormancy** an organism reduces its metabolic state to a minimum level to survive unfavorable conditions.) Similarly, in certain

tropical climates with pronounced wet and dry seasons, the aerial parts of herbaceous perennials die back, and the underground parts become dormant during the unfavorable dry season. Other tropical plants, such as orchids, are herbaceous perennials that grow year-round.

All woody plants are perennials, and some of them live for hundreds or even thousands of years. In temperate climates, the aerial stems of woody plants become dormant during the winter. Many temperate woody perennials are **deciduous**; that is, they shed their leaves before winter and produce new stems with new leaves the following spring. Other woody perennials are **evergreen** and shed their leaves over a long period, so some leaves are always present. Because they have permanent woody stems that are the starting points for new growth the following season, many trees attain massive sizes.

In this chapter we focus on the structure, growth, and development of flowering plants, which are vascular plants characterized by flowers, double fertilization, endosperm, and seeds enclosed within fruits (see Chapter 28). We then examine other aspects of flowering plants in Chapters 34 to 38.

33.1 The Plant Body

LEARNING OBJECTIVES

- 1 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.
- 2 Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).
- 3 Describe the structure and functions of the vascular tissue system (xylem and phloem).
- 4 Describe the structure and functions of the dermal tissue system (epidermis and periderm).

The plant body of flowering plants (and other vascular plants) is usually organized into a root system and a shoot system (**FIG. 33-1**). The **root system** is generally underground. The aerial portion, the **shoot system**, usually consists of a vertical stem that bears leaves and, in flowering plants, flowers and fruits that contain seeds.

Each plant typically grows in two different environments: the dark, moist soil and the illuminated, relatively dry air. Plants usually have both roots and shoots because they require resources from both environments. Thus, roots branch extensively through the soil, forming a network that anchors the plant firmly in place and absorbs water and dissolved minerals (inorganic nutrients). Leaves, the flattened organs of photosynthesis, are attached more or less regularly on the stem, where they absorb the sun's light and atmospheric carbon dioxide (CO_2) used in photosynthesis.

The plant body consists of cells and tissues

As in other organisms, the basic structural and functional unit of plants is the cell. Plants have evolved a variety of cell types, each specialized for particular functions. Plant cells are organized into tissues. A **tissue** is a group of cells that forms a structural and functional unit. *Simple tissues* are composed of only one kind of cell, whereas *complex tissues* have two or more kinds of cells.

In vascular plants, tissues are organized into three tissue systems, each of which extends throughout the plant body (**FIG. 33-2**). Each tissue system contains two or more kinds of tissues (**TABLE 33-1** on page 714). Most of the plant body is composed of the **ground tissue system**, which has a variety of functions, including photosynthesis, storage, and support. The **vascular tissue system**, an intricate conducting system that extends throughout the plant body, is responsible for conduction of various substances, including water, dissolved minerals, and food (dissolved sugar). The vascular tissue system also functions in strengthening and supporting the plant. The **dermal tissue system** provides a covering for the plant body.

Roots, stems, leaves, flower parts, and fruits are **organs** because each is composed of all three tissue systems. The tissue systems of different plant organs form an interconnected network throughout the plant. For example, the vascular tissue system of a leaf is continuous with the vascular tissue system of the stem to which it is attached, and the vascular tissue system of the stem is continuous with the vascular tissue system of the root.

The ground tissue system is composed of three simple tissues

The bulk of a herbaceous plant is its ground tissue system, which is composed of three tissues: parenchyma, collenchyma, and sclerenchyma (**TABLE 33-2** on pages 714 and 715). These tissues can be distinguished by their cell wall structures. Recall that plant cells are surrounded by a cell wall that provides structural support (see Chapter 4). A growing plant cell secretes a thin *primary cell wall*, which stretches and expands as the cell increases in size. After the cell stops growing, it sometimes secretes a thick, strong *secondary cell wall*, which is deposited *inside* the primary cell wall—that is, between the primary cell wall and the plasma membrane (see Fig. 4-30).

Plant cell walls have several important roles. As discussed later in this chapter, cell walls are involved in growth; the ability of primary cell walls to expand allows cells to increase in size. Scientists are increasingly aware that **signal transduction** takes place in plant cell walls because many carbohydrate and protein molecules in plant cell walls communicate with other molecules both inside and outside the cell. The cell wall is also the first line of defense against disease-causing organisms.

Parenchyma cells have thin primary walls

Parenchyma tissue, a simple tissue composed of parenchyma cells, is found throughout the plant body and is the most common type of cell and tissue (**FIG. 33-3a** on page 716). The soft parts of a plant, such as the edible part of an apple or a potato, consist largely of parenchyma.

Parenchyma cells perform several important functions, such as photosynthesis, storage, and secretion. Parenchyma cells that function in photosynthesis contain green chloroplasts, whereas nonphotosynthetic parenchyma cells lack chloroplasts and are often colorless. Materials stored in parenchyma cells include starch grains, oil droplets, water, and salts, which are sometimes visible as crystals. Resins, tannins, hormones, enzymes, and sugary nectar are examples of substances that may be secreted

Key Point

During the evolution of plants, the root and shoot systems specialized to obtain resources from the soil and air, respectively.

Figure 33-1 The plant body

A plant body consists of a root system, usually underground, and a shoot system, usually aerial. Shown is mouse-ear cress (*Arabidopsis thaliana*), a small plant in the mustard family that is a model plant for biological research. *Arabidopsis* is native to North Africa and Eurasia and has been naturalized (was introduced and is now growing in the wild) in California and the eastern half of the United States.

CONNECT What resources required for photosynthesis do plants obtain from the air? from the soil?

by parenchyma cells. The various functions of parenchyma require that parenchyma cells be alive and metabolically active.

Parenchyma cells have the ability to *differentiate* into other kinds of cells, particularly when a plant has been injured. If xylem (water-conducting) cells are severed, for example, adjacent parenchyma cells may divide and differentiate into new xylem cells within a few days. (Recall from Chapter 17 that it is possible

to induce certain plant cells to become the equivalent of embryonic stem cells that can then differentiate into specialized cells.)

Collenchyma cells have unevenly thickened primary walls Collenchyma tissue, a simple plant tissue composed of collenchyma cells, is an extremely flexible structural tissue that provides much of the support in soft, nonwoody plant organs

Key Point

The tissue systems are continuous throughout the plant. For example, the vascular tissue system in a leaf is continuous with the vascular tissue system in the stem to which it is attached.

Figure 33-2 The three tissue systems in the plant body

This figure shows the distribution of the ground tissue system, vascular tissue system, and dermal tissue system in a herbaceous eudicot such as *Arabidopsis*.

PREDICT What do you think would happen if the vascular tissue system were to become discontinuous in the stem but the dermal and ground tissue systems were to remain intact?

(FIG. 33-3b on page 716). Support is crucial for plants, in part because it lets them grow upward to compete with other plants for available sunlight in a plant-crowded area. Plants lack the bony skeletal system typical of many animals; instead, individual cells, including collenchyma cells, support the plant body.

Collenchyma cells, which are usually elongated, are alive at maturity. Their primary cell walls are unevenly thickened and are especially thick in the corners. Collenchyma is not found uniformly throughout the plant and often occurs as long strands near stem surfaces and along leaf veins. The “strings” in a celery stalk, for example, consist of collenchyma tissue.

Sclerenchyma cells have both primary walls and thick secondary walls Another simple plant tissue specialized for structural support is **sclerenchyma** tissue, whose

cells have both primary and secondary cell walls. The root of the word *sclerenchyma* is derived from the Greek word *sclero*, meaning “hard.” The secondary cell walls of sclerenchyma cells become strong and hard because of extreme thickening. *Pits*, which are thin areas where secondary walls did not develop, allow an exchange of substances between adjacent living sclerenchyma cells. Mature sclerenchyma cells are unable to stretch or elongate. At functional maturity, when sclerenchyma tissue is providing support for the plant body, its cells are often dead.

Sclerenchyma tissue may be located in several areas of the plant body. Two types of sclerenchyma cells are sclereids and fibers. **Sclereids** are cells of variable shape common in the shells of nuts and in the stones of fruits such as cherries and peaches. The slightly gritty texture of pears results from the presence of clusters

Table 33-1 Tissue Systems, Tissues, and Cell Types of Flowering Plants

Tissue System	Tissue	Cell Types	Main Functions of Tissue
Ground tissue system	Parenchyma tissue	Parenchyma cells	Storage, secretion, photosynthesis
	Collenchyma tissue	Collenchyma cells	Support
	Sclerenchyma tissue	Sclerenchyma cells (sclereids or fibers)	Support, strength
Vascular tissue system	Xylem	Tracheids Vessel elements Xylem parenchyma cells Fibers (sclerenchyma cells)	Conduction of water and nutrient minerals, support Conduction of water and nutrient minerals, support Storage Support, strength
	Phloem	Sieve tube elements Companion cells Phloem parenchyma cells Fibers (sclerenchyma cells)	Conduction of sugar in solution, support May control functioning of sieve tube elements, loading sugar into sieve tube elements Storage Support, strength
Dermal tissue system	Epidermis	Epidermal cells Guard cells Trichomes	Protective covering over surface of plant body Regulate stomata Variable functions
	Periderm	Cork cells Cork cambium cells Cork parenchyma cells	Protective covering over surface of plant body Meristematic (form new cells) Storage

Table 33-2 Cell Types in the Ground Tissue System

Parenchyma cell

Description

Living, actively metabolizing; thin primary cell walls

Functions

Storage; secretion, and/or photosynthesis

Location and comments

Throughout the plant body; shown is an LM of a stamen hair of a spiderwort (*Tradescantia virginiana*) flower; note the large pigmented vacuole; the nucleus is not inside the vacuole but is lying on top of the vacuole

Parenchyma cell

Description

Living, actively metabolizing; thin primary cell walls

Functions

Storage; secretion; photosynthesis

Location and comments

Throughout the plant body; shown is an LM of leaf cells from an aquatic plant (*Elodea*); note the many chloroplasts in the thin layer of cytoplasm surrounding the large, transparent vacuole

Parenchyma cell

Description

Living, actively metabolizing; thin primary cell walls

Functions

Storage; secretion; photosynthesis

Location and comments

Throughout the plant body; shown is an LM of a cross section of part of a buttercup (*Ranunculus*) root; note the starch grains filling the cells

Continued

Table 33-2 Cell Types in the Ground Tissue System (*continued*)

Collenchyma cell

Description

Living; unevenly thickened primary cell walls

Function

Elastic support

Location and comments

Just under stem epidermis; shown is an LM of a cross section of an elderberry (*Sambucus*) stem; note the unevenly thickened cell walls that are especially thick in the corners, making the cell contents assume a rounded shape in cross section

Sclereid (sclerenchyma cell)

Description

May be living or dead at maturity; thick secondary cell walls; lacks secondary wall at pits

Functions

Strength; sclereid-rich tissue is hard and inflexible

Location and comments

Shells of walnuts and coconuts; pits of cherries and peaches; shown is an LM of living sclereids in a section through a cherry (*Prunus avium*) pit

Fiber (sclerenchyma cell)

Description

Often dead at maturity; thick secondary cell walls; fewer pits than in sclereids

Functions

Support; provides strength

Location and comments

Throughout the plant body; common in stems and certain leaves; shown is an LM of a cross section through a clump of fibers from a century plant (*Agave*) leaf

of sclereids. **Fibers**, which are long, tapered cells that often occur in patches or clumps, are particularly abundant in the wood, inner bark, and leaf ribs (veins) of flowering plants (FIG. 33-3c).

Cells of the three simple tissues vary in their cell wall chemistry Parenchyma, collenchyma, and sclerenchyma cells can be distinguished by the chemistry of their cell walls. Cell walls may contain cellulose, hemicelluloses, pectin, and lignin. **Cellulose**, the most abundant polymer in the world, accounts for about 40% to 60% of the dry weight of plant cell

walls. As discussed in Chapter 3, cellulose is a **polysaccharide** composed of glucose units joined by β -1,4 bonds. Each cellulose molecule consists of thousands of glucose subunits joined to form a flat, ribbonlike chain. From 40 to 70 of these chains lie parallel to one another and connect by hydrogen bonding to form a *cellulose microfibril*, a strong, tiny strand visible under the electron microscope (see Fig. 3-10a).

Cellulose microfibrils are cemented together by a matrix of hemicelluloses and pectins. *Hemicelluloses* are a group of polysaccharides that are more soluble than cellulose. Hemicelluloses

(a) **Parenchyma cells** have thin primary cell walls. They vary in size and structure, depending on their various functions within the plant body.

(b) **Collenchyma cells** in longitudinal section (left) and cross section (right). Note the elongated cells, evident in longitudinal section, and the unevenly thickened primary cell walls, evident in cross section.

(c) **Sclerenchyma cells** (fibers) in longitudinal section (left) and cross section (right). Mature fibers have thick secondary cell walls, are often dead at functional maturity, and therefore lack nuclei and cytoplasm; the lumen is the space formerly occupied by the living cell.

Figure 33-3 Cell types: parenchyma, collenchyma, and sclerenchyma

vary in their chemical composition from one species to another. Some hemicelluloses are composed of *xyloglucan*, which consists of a backbone of β -1,4-glucose molecules to which side chains of *xylose*, a 5-carbon sugar, are attached. Despite their name, the chemical structure of the hemicelluloses is significantly different from that of cellulose. *Pectin*, another cementing polysaccharide, is less variable in its monomer composition than are the hemicelluloses. Pectin monomer units are α -*galacturonic acid*, a 6-carbon molecule that is a derivative of glucose.

An important component of secondary plant cell walls, particularly those of wood, is **lignin**. Composing as much as 35% of the dry weight of the secondary cell wall, lignin is a strengthening polymer made up of monomers derived from certain amino acids. Scientists have not yet determined the exact chemical structure of lignin because it is hard to remove from cellulose and other cell wall materials to which it is covalently bound.

Having discussed the four main components in plant cell walls, we can now generalize about the cell chemistry of

parenchyma, collenchyma, and sclerenchyma cells. The thin primary cell walls of parenchyma cells contain predominantly cellulose, although they also contain hemicelluloses and pectin. Both parenchyma and collenchyma cells have primary cell walls, but their walls are chemically distinct because the thickened areas of collenchyma walls contain large quantities of pectin in addition to cellulose and hemicelluloses. The thick secondary walls of sclerenchyma cells are chemically different because they are rich in lignin in addition to cellulose, hemicelluloses, and pectin.

The vascular tissue system consists of two complex tissues

The **vascular tissue system**, which is embedded in the ground tissue, transports needed materials throughout the plant via two complex tissues: xylem and phloem (TABLE 33-3). Both xylem and phloem are continuous throughout the plant body. (Chapter 35 discusses the mechanisms of transport in xylem and phloem.)

The conducting cells in xylem are tracheids and vessel elements

Xylem conducts water and dissolved minerals from the roots to the stems and leaves and provides structural support. In flowering plants, xylem is a complex tissue composed of four cell types: tracheids, vessel elements, parenchyma cells, and fibers. Two of

the four cell types found in xylem, the **tracheids** and **vessel elements**, conduct water and dissolved minerals. Xylem also contains fibers that provide support, and parenchyma cells, known as *xylem parenchyma*, that perform storage functions.

Tracheids and vessel elements are highly specialized for conduction. As they develop, both types of cells undergo **apoptosis**, or programmed cell death. As a result, mature tracheids and vessel elements are dead and therefore hollow; only their cell walls remain. Tracheids, the chief water-conducting cells in gymnosperms (such as pines) and seedless vascular plants (such as ferns), are long, tapering cells located in patches or clumps (FIG. 33-4a). Water is conducted upward, from roots to shoots, passing from one tracheid into another through wide pits.

In addition to tracheids, flowering plants possess extremely efficient vessel elements (FIG. 33-4b). The cell diameters of vessel elements are usually greater than those of tracheids. Vessel elements are hollow, but unlike tracheids, the end walls have holes, known as *perforations*, or are absent. Vessel elements are stacked

Table 33-3 Selected Cell Types in the Vascular Tissue System

John D. Cunningham/Visuals Unlimited/Getty Images

Tracheid

Description

Dead at maturity; lacks secondary wall at pits

Functions

Conduction of water and nutrient minerals; support

Location and comments

Occurs in clumps in xylem throughout plant body; shown is an LM of a longitudinal section of tracheids from white pine (*Pinus strobus*) wood

James Mauseth, University of Texas

Vessel element

Description

Dead at maturity; end walls have perforations; lacks secondary wall at pits

Functions

Conduction of water and nutrient minerals; support

Location and comments

Xylem throughout plant body; vessel elements are more efficient than tracheids in conduction; shown is an LM of a longitudinal section of two vessel elements from an unidentified woody eudicot

James Mauseth, University of Texas

Sieve tube element

Description

Living but lacks nucleus and other organelles at maturity; end walls are sieve plates

Function

Conduction of sugar in solution

Location and comments

Phloem throughout plant body; shown is an LM of a longitudinal section through a clump of sieve tube elements in a squash (*Cucurbita*) petiole (leaf stalk)

Biophoto Associates/Getty Images

Companion cell

Description

Living; has cytoplasmic connections with sieve tube element

Function

Assists in moving sugars into and out of sieve tube element

Location and comments

Phloem throughout plant body; shown is an LM of phloem from a squash (*Cucurbita*) stem in cross section

one on top of the other, and water is conducted readily from one vessel element into the next. A stack of vessel elements, called a **vessel**, resembles a miniature water pipe. Vessel elements also have pits in their side walls that permit the lateral transport (sideways movement) of water from one vessel to another.

Sieve tube elements are the conducting cells of phloem Phloem conducts food materials—that is, carbohydrates formed in photosynthesis—throughout the plant and provides structural support. In flowering plants phloem is a complex tissue composed of four cell types: sieve tube elements, companion cells, fibers, and phloem parenchyma cells (FIGS. 33-4c and d). Fibers, which are usually extensive in the phloem of herbaceous plants, provide additional structural support for the plant body.

Food materials are conducted in solution—that is, dissolved in water—through the **sieve tube elements**, which are among the most specialized plant cells. Sieve tube elements are joined end to end to form long **sieve tubes**. The cells' end walls, called *sieve plates*, have a series of holes through which cytoplasm extends from one sieve tube element into the next. Sieve tube elements are living at maturity, but many of their organelles, including the nucleus, vacuole, mitochondria, and ribosomes, disintegrate or shrink as they mature.

Sieve tube elements are among the few eukaryotic cells that can function without nuclei. These cells typically live for less than a year. There are, however, notable exceptions. Certain palms have sieve tube elements that remain alive for approximately one hundred years.

Adjacent to each sieve tube element is a **companion cell** that assists in the functioning of the sieve tube element. The companion cell is a living cell, complete with a nucleus. This nucleus is thought to direct the activities of both the companion cell and sieve tube element. Numerous **plasmodesmata**—cytoplasmic connections through which cytoplasm extends from one cell to another (see Fig. 5-24)—link a companion cell with its adjoining sieve tube element. The companion cells play an essential role in moving sugar into the sieve tube elements for transport to other parts of the plant.

The dermal tissue system consists of two complex tissues

The **dermal tissue system**—the epidermis and periderm—provides a protective covering over plant parts (TABLE 33-4). In herbaceous plants the dermal tissue system is a single layer of cells called the epidermis. Woody plants initially produce

(a) **Tracheid (xylem cell).** The tracheid is opened to reveal the cell's appearance in cross section. At maturity, tracheids are usually dead.

(b) **Vessel element (xylem cell).** The end walls of vessel elements are perforated. Vessel elements are joined end to end, from roots to leaves and other shoot parts.

(c) **Sieve tube element, showing the sieve plate.** Sieve tube elements are joined end to end to form sieve tubes.

(d) **Longitudinal section of phloem tissue.** Sieve tube elements, companion cells, and phloem parenchyma cells. Fiber cells are not shown.

Figure 33-4 Longitudinal views of cell types in xylem and phloem tissues

Table 33-4 Selected Cell Types in the Dermal Tissue System

Epidermal cell

Description

Relatively unspecialized cell with thin primary wall; outer wall often thicker and covered by a noncellular waxy layer (cuticle)

Functions

Protective covering over surface of plant body; helps reduce water loss

Location and comments

Epidermis is usually one cell thick; shown is an LM of a cross section through epidermis of an ivy (*Hedera helix*) stem

Guard cell

Description

Chloroplast-containing cell that occurs in pairs; pair changes shape to open and close stomatal pore

Function

Opens and closes stomatal pore

Location and comments

Epidermis of stems and leaves; shown is an LM of the epidermis of a spiderwort (*Tradescantia virginiana*) leaf

Trichome

Description

Hair or other epidermal outgrowth; may be unicellular or multicellular; occurs in variety of sizes and shapes

Functions

Varied; absorption; secretion; excretion; protection; reduction of water loss

Location and comments

Epidermis; shown is an SEM of a nettle (*Solanum carolinense*) leaf, which has trichomes that break off inside the skin of animals and inject irritating substances that cause a stinging sensation

Cork cell

Description

Dead at maturity; cell walls impregnated with waterproof material (suberin)

Functions

Reduces water loss and prevents disease-causing organisms from penetrating

Location and comments

Produced in large numbers; cork often forms just under the epidermis; replaces epidermis in older stems and roots; shown is an LM of a cross section through the periderm of a calico flower (*Aristolochia elegans*) stem

an epidermis, but it splits apart as a result of the production of additional woody tissues inside the epidermis as the plant increases in girth. Periderm, which replaces the epidermis in the stems and roots of older woody plants, composes the outer bark.

Epidermis is the outermost layer of a herbaceous plant The epidermis is a complex tissue composed primarily of relatively unspecialized living cells. Dispersed among these cells are more specialized guard cells and outgrowths called trichomes (discussed later). In most plants the epidermis

consists of a single layer of flattened cells (**FIG. 33-5**). Epidermal cells generally contain no chloroplasts and are therefore transparent, so light can penetrate the interior tissues of stems and leaves. In both stems and leaves, photosynthetic tissues lie *beneath* the epidermis.

An important requirement of the aerial parts (stems, leaves, flowers, and fruits) of a plant is the ability to control water loss. Epidermal cells of aerial parts secrete a waxy **cuticle** over the surface of their exterior walls; this waxy layer greatly restricts water loss from plant surfaces.

Although the cuticle is extremely efficient at preventing most water loss through epidermal cells, it also slows the diffusion of CO₂, needed for photosynthesis, from the atmosphere into the leaf or stem. The diffusion of CO₂ is facilitated by **stomata** (sing., *stoma*). Stomata are minute pores in the epidermis that are surrounded by two cells called **guard cells** (see Fig. 34-5). Many gases, including CO₂, oxygen, and water vapor, pass through the stomata by diffusion. Stomata are generally open during the day when photosynthesis is occurring, and the water loss that also takes place when stomata are open provides some evaporative cooling. At night, stomata usually

close. In drought conditions, the need to conserve water overrides the need to cool the leaves and exchange gases. Thus, during a drought, the stomata close in the daytime. Stomata are discussed in greater detail in Chapter 34.

The epidermis also contains special outgrowths, or hairs, called **trichomes**, which occur in many sizes and shapes and have a variety of functions. Plants that tolerate salty environments such as the seashore often have specialized trichomes on their leaves to remove excess salt that accumulates in the plant. The presence of trichomes on the aerial parts of desert plants may increase the reflection of light off the plants, thereby cooling the internal tissues and decreasing water loss. Other trichomes have a protective function. For example, the trichomes on stinging nettle leaves and stems contain irritating substances that may discourage herbivorous animals from eating the plant. **Root hairs** are simple, unbranched trichomes that increase the surface area of the root epidermis (which comes into contact with the soil) for more effective water and mineral absorption.

Periderm replaces epidermis in woody plants

Periderm, a tissue that can be anywhere from several to many cell layers thick, forms under the epidermis to provide a new protective covering as the epidermis is destroyed. As a woody plant continues to increase in girth, its epidermis is sloughed off, exposing the periderm. Periderm forms the outer bark of older stems and roots. It is a complex tissue composed mainly of cork cells and cork parenchyma cells. **Cork cells** are dead at maturity, and their walls are heavily coated with a waterproof substance called *suberin*, which helps reduce water loss. **Cork parenchyma** cells function primarily in storage. Periderm is discussed further in Chapters 35 and 36.

Figure 33-5 Cell types: epidermal cells

Epidermal cells from three different plants. Note that regardless of the cell shape, epidermal cells fit tightly together.

CHECKPOINT 33.1

- What are some of the functions of roots? of shoots?
- What are the three tissue systems in plants? Describe the functions of each.
- How do parenchyma, collenchyma, and sclerenchyma tissues differ in cell structure and function?
- What are the functions of xylem and phloem? Describe the conducting cells that occur in each of these complex tissues.
- **CONNECT** How are epidermis and periderm alike? How are they different?

33.2 Plant Meristems

LEARNING OBJECTIVES

- 5 State how growth in plants differs from growth in animals.
- 6 Distinguish between primary and secondary growth.
- 7 Distinguish between apical meristems and lateral meristems.

One difference between plants and animals is the *location* of growth. When plants grow, their cells divide only in specific areas, called **meristems**, which are composed of cells whose primary function is to form new cells by mitotic division. (In contrast, when a young animal is growing, all parts of its body grow, although not necessarily at the same rate.) Meristematic cells, also known as *stem cells*, do not differentiate. Instead, they retain the ability to divide by mitosis, a trait that many differentiated cells lose. The persistence of mitotically active meristems means that plants, unlike most animals, can grow throughout their entire lifespan.

This ability of roots and stems to grow throughout a plant's life is known as **indeterminate growth**. In contrast, many leaves and flowers have **determinate growth**; that is, they stop growing after reaching a certain size. The size of leaves and flowers with determinate growth varies from species to species and from individual to individual, depending on the plant's genetic programming and on environmental conditions such as availability of sunlight, water, and essential minerals.

Two kinds of meristematic growth may occur in plants. **Primary growth** is an increase in stem and root length. All plants have primary growth, which produces the entire plant body in herbaceous plants and the young, soft shoots and roots in woody trees and shrubs. **Secondary growth** is an increase in the girth of a plant. For the most part, only gymnosperms and woody eudicots have secondary growth. (Woody eudicots include such trees and shrubs as oak, sycamore, ash, cherry, apple, beech, and maple.)

Tissues produced by secondary growth compose the wood and bark, which make up most of the bulk of trees and shrubs. A few annuals—geraniums and sunflowers, for example—undergo limited secondary growth even though they lack obvious wood and bark tissues.

Primary growth takes place at apical meristems

Primary growth occurs as a result of the activity of **apical meristems**, areas located at the tips of roots and shoots, including within the buds of stems. **Buds** are dormant embryonic shoots that eventually develop into branches.

Primary growth is evident when a root tip is examined (FIG. 33-6). A protective layer of cells called a **root cap** covers the root tip. Directly behind the root cap is the root apical meristem, which consists of meristematic cells. Meristematic cells, which are cube shaped, remain small because they are continually dividing. (In meristems, as daughter cells begin to enlarge, one or both will divide again.)

Farther from the root tip, just behind the area of cell division, is an area of cell elongation where the cells have been displaced from the meristem. Here the cells are no longer dividing but instead are growing longer, pushing the root tip ahead of them, deeper into the soil. Some differentiation also begins to occur in the area of cell elongation, and immature tissues such as differentiating xylem and phloem become evident. The tissue systems continue to develop and differentiate into primary tissues (epidermis, xylem, phloem, and ground tissues) of the adult plant. Farther from the tip, behind the

Figure 33-6 A root tip

The root apical meristem (where cells divide and thus increase in number) is protected by a root cap. Farther from the tip is an area of cell elongation where cells enlarge and begin to differentiate. Note the young root hairs in the area of cell maturation, which has fully mature, differentiated cells.

area of cell elongation, most cells have completely differentiated and are fully mature. Root hairs are evident in this area.

A shoot apex (such as the terminal bud) is quite different in appearance from a root tip (FIG. 33-7). A dome of minute, regularly arranged meristematic cells—the shoot apical meristem—is located in each shoot apex. *Leaf primordia* (developing leaves) and *bud primordia* (developing buds) arise from the shoot apical meristem. The tiny leaf primordia cover and protect the shoot apical meristem. As the cells formed by the shoot apical meristem elongate, the shoot apical meristem is pushed upward. Subsequent cell divisions produce additional stem tissue and cause new leaf and bud primordia to appear. Farther from the stem tip, the immature cells differentiate into the three tissue systems of the mature plant body.

Secondary growth takes place at lateral meristems

Trees and shrubs undergo both primary and secondary growth. These plants increase in length by primary growth and increase in girth by secondary growth. The increase in girth, which occurs in areas that are no longer elongating, is due to cell divisions that take place in **lateral meristems**, areas extending along the entire length of the stems and roots except at the tips. Two lateral meristems, the vascular cambium and the cork cambium, are responsible for secondary growth, which is the formation of secondary tissues: secondary xylem, secondary phloem, and periderm (FIG. 33-8).

Figure 33-7 A shoot apex

LM of a longitudinal section through a shoot apex of *Coleus*, showing the shoot apical meristem, leaf primordia, and bud primordia.

The **vascular cambium** is a layer of meristematic cells that forms a long, thin, continuous cylinder within the stem and root. It is located between the wood and bark of a woody plant. Division of cells of the vascular cambium adds more cells to the wood (secondary xylem) and inner bark (secondary phloem).

The **cork cambium**, located in the outer bark, is composed of a thin cylinder or irregular arrangement of meristematic cells. Cells of the cork cambium divide and form **cork cells** toward the outside and one or more underlying layers of **cork parenchyma** cells that function in storage. Collectively, cork cells, cork cambium, and cork parenchyma make up the periderm.

Figure 33-8 Secondary growth

The vascular cambium, a thin layer of cells sandwiched between the wood and bark, produces the secondary vascular tissues: the wood, which is secondary xylem, and the inner bark, which is secondary phloem. The cork cambium produces the periderm, the outer bark tissue that replaces the epidermis in a plant with secondary growth.

We are now ready to give a more precise definition of **bark**. **Bark**, the outermost covering over woody stems and roots, consists of all plant tissues located outside the vascular cambium. Bark has two regions, a living inner bark composed of secondary phloem and a mostly dead outer bark composed of periderm. Chapters 35 and 36 present a more comprehensive discussion of secondary growth.

CHECKPOINT 33.2

- **CONNECT** What is the role of plant meristems? Does animal growth involve meristems?
- How does secondary growth differ from primary growth?
- **CONNECT** How do the functions of apical and lateral meristems relate to primary and secondary growth?

33.3 Development of Form

LEARNING OBJECTIVES

- 8 Distinguish between cell division and cell expansion, and describe the roles of the preprophase band and cellulose microfibrils.
- 9 Describe the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.
- 10 Explain why the model organism *Arabidopsis* is so useful in the study of plant development.

Plants are growing, dynamic organisms. **Development** in plants encompasses all the changes that take place during the entire life of an individual. Of particular interest in developmental biology is the process by which cells specialize and

Figure 33-9 Growth of an *Arabidopsis* seedling into an adult plant

Almost all the differentiated tissues formed after a seed is germinated (often referred to as postembryonic growth) come from a small number of stem cells in the root and shoot apical meristems.

organize into a complex organism. For example, how does a microscopic, unicellular zygote give rise to a multicellular embryo in a seed? (See the stages of embryonic development in a typical eudicot in Figure 37-8.) How does the embryo in the seed give rise to the leaves, stems, and roots of a *juvenile* plant, and what mechanisms underlie the transition from a nonreproductive juvenile plant to an *adult plant* capable of flowering (**FIG. 33-9**)?

We now examine several aspects of plant development that affect form in plants. Flowering is discussed elsewhere in this book (see the ABC model in Chapter 17).

The plane and symmetry of cell division affect plant form

You have seen that plant growth is localized into meristems for cell division. At these sites, the cells undergo cell division in an orderly manner. In the onion root apical meristem,

for example, files of cells can be traced back to the meristem region (**FIG. 33-10**). These cells divided in the same plane to produce each file of cells. Cell divisions in one plane, two planes, or more help establish the tissue patterns that will be produced during development.

How is the plane of cell division for a particular meristematic cell determined? In plant cells a dense array of microtubules forms a **preprophase band** just inside of the plasma membrane, encircling the nucleus much like a belt. (Chapter 4 contains a discussion of the dynamic nature of microtubules.) The preprophase band appears just prior to mitosis and determines the plane in which the cell will divide (**FIG. 33-11**). The preprophase band, which is located where the cell plate will form following mitosis and cytokinesis, also helps orient the mitotic spindle. The preprophase band is a plant characteristic; in animal cells, the orientation of the spindle determines the plane in which cells divide, and there is no preprophase band.

(a) Cells that divide in the same plane form a row, or file, of cells.

(b) A single file of cells in the onion root tip is labeled. If you look closely, you can see many other files.

Figure 33-10 The plane of cell division and the onion root tip
The root apical meristem maintains postembryonic root growth.

The orientation of cellulose microfibrils affects the direction of cell expansion

In plants, growth occurs by both an increase in the number of cells and an increase in cell size. Cell division and cell expansion (also called *elongation*) are governed by a genetic program that interacts with environmental signals from both the external and internal environments.

In growth, a newly formed plant cell absorbs water into its vacuole by osmosis. The water increases the cell's **turgor pressure**, hydrostatic pressure that develops within a walled cell and presses outward against the plasma membrane. Turgor pressure provides a force that exerts pressure on the cell wall and causes it to expand. In an onion root cell, the vacuole increases in size by some 30 to 150 times during elongation.

In growing tissue, the arrangement of cellulose microfibrils in the wall prevents the cell from expanding equally in all directions due to turgor pressure. When the microfibrils in the cell wall are oriented in the same direction, the wall expands perpendicularly to them (FIG. 33-12).

Cell differentiation depends in part on a cell's location

By themselves, cell division and cell expansion would produce only a formless heap of similar cells. The development of plant form is the result of a balanced combination of several fundamental processes that go beyond cell division and cell expansion: cell differentiation and cell determination, and pattern formation and morphogenesis.

The preprophase band of microtubules encircles the nucleus and indicates the plane of an upcoming cell division.

Figure 33-11 Preprophase band

As growth proceeds, cell division gives rise to increasing numbers of cells, which serve as the building blocks of development. At various times, certain cells become biochemically and structurally specialized to carry out specific functions through a process known as **cell differentiation**. Generally, a differentiated animal cell is irreversibly committed to its fate, but that is not the case with plants. As discussed earlier in this chapter, parenchyma cells can differentiate into other kinds of cells, for example, when the plant body is injured.

Cell differentiation occurs through **cell determination**, a series of molecular events in which the activities of certain genes are altered in ways that cause a cell to progressively commit to a particular differentiation pathway. As cell

Figure 33-12 Direction of cell expansion

Following cell division, cellulose microfibrils are deposited into new cell walls in an orderly fashion that permits cell expansion. The orientation of the cellulose microfibrils determines the direction of cell expansion. Note that most of the cellulose microfibrils are oriented transversely in this figure, which results in longitudinal cell expansion.

determination proceeds, a young cell's fate becomes more and more limited, restricting its development to a limited set of tissue types.

During cell differentiation, a cell's physical appearance may or may not change significantly. Nevertheless, when cell determination is complete, a cell becomes structurally and functionally recognizable—as an epidermal cell, for example—and its pattern of gene activity differs from that of other cell types. Thus, differentiated cells of the plant body have **differential gene expression**; that is, different genes are active in different cells at the same time. Differential gene expression is responsible for variations in chemistry, behavior, and structure among cells.

Tissue cultures involve differential gene expression

Cells can be isolated from certain plants and grown in a chemically defined, sterile nutrient medium. In initial experiments with such cultures, plant cells could be kept alive, but they did not divide. Researchers later discovered that adding certain natural materials, such as the liquid endosperm of coconut, also known as coconut milk, induced cells to divide in culture. By the late 1950s, plant cells from a variety of sources could be cultured successfully, dividing to produce a mass of disorganized, relatively undifferentiated cells, or **callus**.

In 1958, F.C. Steward, a plant physiologist at Cornell University, succeeded in generating an entire carrot plant from a single callus cell derived from a carrot root (see Fig. 17-2), thus demonstrating that each plant cell contains a genetic blueprint for all features of an entire organism. His work also showed that an entire plant can be grown from a single cell, provided differential gene expression occurs so that the proper genes are expressed at the appropriate times.

Since Steward's pioneering work, biologists have successfully cultured many plants by using a variety of cell sources. Plants have been regenerated from different tissues, organ explants (excised organs or parts such as root apical meristems), and single cells. Cell and tissue culture techniques help answer many fundamental questions involving growth and development in plants. These techniques also have great practical potential. Using tissue culture, researchers can regenerate many genetically identical plants from the cells of a single, genetically superior plant. Many kinds of plants—from orchids and African violets to coastal redwoods—have been cultured in this way.

Morphogenesis occurs through pattern formation

Cell differentiation by itself does not explain overall plant form. The differentiated cells must become progressively organized, shaping the intricate pattern of tissues and organs that characterizes a multicellular plant. This development of form, in which differentiated cells in specific locations become spatially organized into recognizable structures, is known as **morphogenesis**.

(a) Examples of leaf shapes.

(b) Examples of leaf margins.

Figure 33-13 Leaf variation and pattern formation

Leaves are quite variable in form; there are dozens of different leaf shapes and margins. Leaves on juvenile plants are often shaped differently than those on adult plants, and some adult plants have several leaf shapes on the same individual. Pattern formation, which is under genetic control, is largely responsible for leaf variation. (Also see Figure 34-2 for more examples of variation in leaves.)

Morphogenesis proceeds through the process of **pattern formation**, a series of steps requiring signaling between cells, changes in the shapes and metabolism of certain cells, and precise cell interactions. Pattern formation organizes cells into three-dimensional structures (FIG. 33-13). Depending on their location, cells are exposed to different concentrations of signaling molecules that specify **positional information**, that is, where the cell is located relative to the body's axes. This information affects cell differentiation and tissue formation. Thus, *where* a given cell is located often determines *what* it will become when it matures.

Arabidopsis mutants provide crucial insights into plant development Until the late 1970s, biologists knew little about how genes interact to control development. However, rapid progress in molecular biology led scientists to search for developmental mutants and to apply sophisticated techniques to study them. (A *mutant* is an individual with an abnormal phenotype caused by a gene mutation.) Biologists are now studying how genes are activated, inactivated, and modified to control development. Eventually, scientists expect to reach a major goal of systems biology: understanding how a single cell (a fertilized egg) develops into a multicellular plant.

You may recall from Chapter 17 that mouse-ear cress (*Arabidopsis thaliana*) is the organism most widely used to study the genetic control of development in plants. When

biologists insert cloned foreign genes into *Arabidopsis* cells, the genes integrate into the chromosomes and are expressed. The researchers then induce these transformed cells to differentiate into transgenic plants.

Botanists use chemical mutagens to produce mutant strains and have isolated many developmental mutants of *Arabidopsis*. Consider the *monopteros* (*mp*) gene, which codes for a transcription factor affecting apical–basal pattern formation and the development of vascular tissues. Mutant *mp* seedlings lack basal structures, including a primary root. Such mutant phenotypes have helped scientists identify the genes essential for normal development.

CHECKPOINT 33.3

- Which process typically occurs first, cell differentiation or cell expansion?
- What are some kinds of events that contribute to pattern formation?
- **CONNECT** What is the relationship between pattern formation and morphogenesis?
- Why is *Arabidopsis* such a useful model organism for plant development?

Summary: Focus on Learning Objectives

33.1 The Plant Body (page 711)

- 1 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.
 - The vascular plant body typically consists of a root system and a shoot system. The **root system** is generally underground and obtains water and dissolved minerals for the plant. Roots also anchor the plant firmly in place.
 - The **shoot system** is generally aerial and obtains sunlight and exchanges gases such as CO₂, oxygen, and water vapor. The shoot system consists of a vertical stem that bears leaves and reproductive structures. **Buds**, undeveloped embryonic shoots, develop on stems.
- 2 Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).
 - The **ground tissue system** consists of three tissues with a variety of functions. **Parenchyma** tissue is composed of living parenchyma cells that have thin *primary cell walls*. Functions of parenchyma tissue include photosynthesis, storage, and secretion.
 - **Collenchyma** tissue consists of collenchyma cells with unevenly thickened primary cell walls. This tissue provides flexible structural support.
 - **Sclerenchyma** tissue is composed of sclerenchyma cells—**sclereids** or **fibers**—that have both *primary cell walls* and *secondary cell walls*. Sclerenchyma cells are often dead at maturity but provide structural support.
- 3 Describe the structure and functions of the vascular tissue system (xylem and phloem).
 - The **vascular tissue system** conducts materials throughout the plant body and provides strength and support.
 - **Xylem** is a complex tissue that conducts water and dissolved minerals. The actual conducting cells of xylem are **tracheids** and **vessel elements**.
 - **Phloem** is a complex tissue that conducts sugar in solution. **Sieve tube elements** are the conducting cells of phloem; they are assisted by **companion cells**.
- 4 Describe the structure and functions of the dermal tissue system (epidermis and periderm).
 - The **dermal tissue system** is the outer protective covering of the plant body.
 - The **epidermis** is a complex tissue that covers the herbaceous plant body. The epidermis that covers aerial parts secretes a waxy **cuticle** that reduces water loss. **Stomata** permit gas exchange between the interior of the shoot system and the surrounding atmosphere. **Trichomes** are outgrowths, or hairs, that occur in many sizes and shapes and have a variety of functions.
 - The **periderm** is a complex tissue that covers the plant body in woody plants.

33.2 Plant Meristems (page 720)

- 5 State how growth in plants differs from growth in animals.
 - Growth in plants, unlike that in animals, is localized in specific regions called **meristems**. Meristems are composed of

cells whose primary function is to form new cells by mitotic division.

- 6 Distinguish between primary and secondary growth.
 - **Primary growth** is an increase in stem or root length. Primary growth occurs in all plants.
 - **Secondary growth** is an increase in stem or root girth (thickness). Secondary growth typically occurs in long cylinders of meristematic cells throughout the length of older stems and roots.
- 7 Distinguish between apical meristems and lateral meristems.
 - Primary growth results from the activity of **apical meristems** that are localized at the tips of roots and shoots and within the buds of stems.
 - The two **lateral meristems** responsible for secondary growth are the **vascular cambium** and the **cork cambium**.

33.3 Development of Form (page 722)

- 8 Distinguish between cell division and cell expansion, and describe the roles of the preprophase band and cellulose microfibrils.
 - Growth occurs by both cell division (an increase in the number of cells) and cell expansion (an increase in cell size).
 - In plant cells, a dense array of microtubules forms a **preprophase band** just inside of the plasma membrane. The preprophase band appears just prior to mitosis and determines the plane in which the cell will divide.
 - Absorption of water into a cell's vacuole increases the **turgor pressure**, which exerts pressure on the cell wall. The arrangement of cellulose microfibrils in the wall prevents the wall from expanding equally in all directions. When microfibrils are oriented the same way, the wall expands perpendicular to the microfibrillar orientation.
- 9 Describe the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.
 - In **cell differentiation**, cells become biochemically and structurally specialized to carry out specific functions. Cell differentiation occurs through **cell determination**, a series of molecular events in which the activities of certain genes are altered in ways that cause a cell to progressively commit to a particular differentiation pathway.
 - The development of form, in which differentiated cells in specific locations become spatially organized into recognizable structures, is known as **morphogenesis**. Morphogenesis proceeds through the process of **pattern formation**, a series of steps requiring signaling between cells, changes in the shapes and metabolism of certain cells, and precise cell interactions.
- 10 Explain why the model organism *Arabidopsis* is so useful in the study of plant development.
 - Botanists have isolated many developmental mutants of *Arabidopsis*. Such mutant phenotypes have helped scientists identify genes essential for normal development.

Test Your Understanding

Know and Comprehend

1. Most of the plant body consists of the _____ tissue system. (a) ground (b) vascular (c) periderm (d) dermal (e) cortex
2. The cell walls of parenchyma cells (a) contain large quantities of pectin in the thickened corners (b) are rich in lignin but do not contain hemicelluloses and pectin (c) are predominantly cellulose, although they also contain hemicelluloses and pectin (d) contain cellulose, hemicelluloses, and lignin in approximately equal amounts (e) contain hemicelluloses, pectin, and lignin but no cellulose
3. Which tissue system provides a covering for the plant body? (a) ground (b) vascular (c) periderm (d) dermal (e) cortex
4. The two simple tissues that are specialized for support are (a) parenchyma and collenchyma (b) collenchyma and sclerenchyma (c) sclerenchyma and parenchyma (d) parenchyma and xylem (e) xylem and phloem
5. Sclereids and fibers are examples of which plant tissue? (a) parenchyma (b) collenchyma (c) sclerenchyma (d) xylem (e) epidermis
6. Which of the following statements about the vascular tissue system is *not* true? (a) xylem and phloem are continuous throughout the plant body (b) xylem not only conducts water and dissolved minerals but also provides support (c) four cell types occur in phloem: sieve tube elements, companion cells, tracheids, and vessel elements (d) sieve tube elements lack nuclei (e) vessel elements are hollow, and their end walls have perforations or are entirely dissolved away
7. Minute pores known as _____ dot the surface of the epidermis of leaves and stems; each pore is bordered by two _____. (a) stomata; guard cells (b) stomata; fibers (c) sieve tube elements; companion cells (d) sclereids; guard cells (e) cuticle; guard cells
8. Primary growth, an increase in the length of a plant, occurs at the (a) cork cambium (b) apical meristem (c) vascular cambium (d) lateral meristem (e) periderm
9. The preprophase band (a) appears just prior to mitosis in both plant and animal cells (b) determines the plane in which the cell will divide (c) attaches to cellulose microfibrils in the cell wall (d) is an essential part of pattern formation in plants (e) increases a cell's turgor pressure
10. Cell differentiation occurs through _____, whereas morphogenesis involves _____. (a) pattern formation; cell determination (b) cell division; cell expansion (c) cell expansion; pattern formation (d) cell determination; cell division (e) cell determination; pattern formation

11. The *monopteros* mutant (a) lacks a primary root (b) develops normally until the plant becomes reproductive (c) has abnormal leaf morphogenesis (d) was discovered in rice after its genome was sequenced (e) is one of only two developmental mutants known in *Arabidopsis*.

Apply and Analyze

12. Label the three tissue systems in this leaf cross section.

13. **VISUALIZE** Sketch a roughly cuboidal cell preparing to divide. Indicate the orientation of the preprophase band and the site where the new cell walls of the daughter cells will form.
14. **VISUALIZE** Sketch a cell preparing to expand. Indicate the orientation of the cellulose microfibrils and use a double-headed arrow to indicate the direction of subsequent cell elongation.

Evaluate and Synthesize

15. A couple carved a heart with their initials into a tree trunk 4 ft above ground level; the tree was 25 ft tall at the time. Twenty years later the tree was 50 ft tall. How far above the ground were the initials then? Explain your answer.
16. Sclerenchyma in plants is the functional equivalent of bone in humans (both sclerenchyma and bone provide support). However, sclerenchyma is dead, whereas bone is living tissue. What are some of the advantages of a plant having dead support cells? Can you think of any disadvantages? Explain your answer.
17. **EVOLUTION LINK** Flowering plants have both tracheids and vessel elements in their xylem. Conifers, which evolved earlier than flowering plants, have tracheids only. Do these differences in xylem structure help explain the difference in the success of these two plant groups? Explain your answer.
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** Why is knowledge gained from sequencing the *Arabidopsis* genome important even though *Arabidopsis* has no commercial value?

34 Leaf Structure and Function

Plants allocate many resources into the production of leaves that are often short-lived. Each year, a large maple tree, for example, may produce 47 m² (500 ft²) of leaves, which may weigh more than 113 kg (250 lb). The metabolic cost of producing so many leaves is high, but necessary. Simply put, leaves are essential to the tree's survival, so plants must invest in their production.

In most vascular plants, leaves are the primary organs to effectively collect solar energy and convert it into chemical energy. That is, leaves gather the sunlight necessary for **photosynthesis**, the biological process that converts radiant energy into the chemical energy of carbohydrate molecules. Plants use these molecules as starting materials to synthesize all other organic compounds and as fuel to provide energy for metabolism. During a single summer, the leaves of a maple tree will fix about 454 kg (1000 lb) of carbon dioxide (CO₂) into organic compounds.

The structure of a leaf is superbly adapted for its primary function of photosynthesis. Most leaves are thin and flat, a shape that allows optimal absorption of light energy and the efficient internal diffusion of gases such as CO₂ and O₂. As a result of their ordered arrangement on the stem, leaves efficiently catch the sun's rays with a minimum of "interference" from neighboring leaves. The leaves form an intricate green mosaic, bathed in sunlight and atmospheric gases.

To control water loss, a thin, transparent layer of wax covers the leaf surface. Such structural adaptations are compromises between competing needs, and some features that optimize photosynthesis promote water loss. For example, plants have minute pores that allow gas exchange for photosynthesis, but these openings also let water vapor escape into the atmosphere. Thus, leaf structure represents a trade-off between photosynthesis and water conservation.

In this chapter we examine leaf form and function. Leaf form is highly variable, and thousands of different leaf shapes have evolved over millions of years. Despite this diversity, most leaves "work" in the same way, and their internal structures (see photograph) support this similarity in function.

KEY CONCEPTS

- 34.1** Leaf structure reflects its primary function of photosynthesis.
- 34.2** Opening and closing of stomata affect carbon dioxide availability in the daily cycle of photosynthesis.
- 34.3** Transpiration, the loss of water vapor from leaf surfaces, keeps leaves from becoming overheated and promotes water transport in the plant. Guttation is the exudation of liquid water from leaf margins.
- 34.4** Leaf abscission is the seasonal removal of deciduous leaves.
- 34.5** Some leaves are modified for special functions in addition to photosynthesis and transpiration.

PHOTO: Colorized SEM of the interior of a stinging nettle. The loose arrangement of internal cells in stinging nettle (*Urtica dioica*) optimizes the diffusion of necessary raw materials such as carbon dioxide and water into photosynthetic cells. Peter Bond/Science Source

34.1 Leaf Form and Structure

LEARNING OBJECTIVES

- 1 Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.
- 2 Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem) and sketch how they are arranged in a leaf cross section.
- 3 Compare leaf anatomy in eudicots and monocots.
- 4 Relate leaf structure to its function of photosynthesis.

Foliage leaves are the most variable of plant organs, so much so that plant biologists have developed specific terminology to describe their shapes, margins (edges), vein patterns, and the way they attach to stems. Because each leaf is characteristic of the species on which it grows, many plants can be identified by their leaves alone. Leaves may be round, needlelike, scalelike, cylindrical, heart-shaped, fan-shaped, or thin and narrow. They vary in size from those of the raphia palm (*Raphia ruffia*), whose leaves often grow more than 20 m (65 ft) long, to those of water-meal (*Wolffia*), whose leaves are so small that 16 of them laid end to end measure only 2.5 cm (1 in.).

The broad, flat portion of a leaf is the **blade**; the stalk that attaches the blade to the stem is the **petiole**. Some leaves also have **stipules**, which are leaflike outgrowths usually present in pairs at the base of the petiole (FIG. 34-1). Some leaves do not have petioles (i.e., the blades are attached directly to the stem) or stipules; leaves without a petiole are said to be *sessile*.

Leaves may be *simple* (having a single blade) or *compound* (having a blade divided into two or more leaflets) (FIG. 34-2a). Sometimes it is difficult to tell whether a plant has formed one compound leaf or a small stem bearing several simple leaves. One easy way to determine if a plant has simple or compound leaves is to look for axillary buds, so-called because each develops in a leaf *axil* (the angle between the stem and petiole). Axillary buds form at the base of a leaf, whether it is simple or compound. However, axillary buds never develop at the base of leaflets. Also, the leaflets of a compound leaf lie in a single plane (you can lay a compound leaf flat on a table), whereas simple leaves usually are not arranged in one plane on a stem.

Leaves are arranged on a stem in one of three possible ways (FIG. 34-2b). Plants such as beeches and walnuts have an *alternate leaf arrangement*, with one leaf at each **node**, the area of the stem where one or more leaves are attached. In an *opposite leaf arrangement*, as occurs in maples and ashes, two leaves grow at each node. In a *whorled leaf arrangement*, as in catalpa trees, three or more leaves grow at each node.

Leaf blades may possess *parallel venation*, in which the primary **veins**—strands of vascular tissue—run approximately parallel to one another (generally characteristic of monocots), or *netted venation*, in which veins are branched in such a way that they resemble a net (generally characteristic of eudicots; FIG. 34-2c).¹ Netted veins can be *pinnately netted*, with major veins branching off in succession along the entire length of the **midvein** (main or central vein of a leaf), or *palmately netted*, with several major veins radiating out from one point.

Figure 34-1 Parts of a leaf

A geranium leaf consists of a blade, a petiole, and two stipules at the base of the leaf. Note the axillary bud in the leaf axil.

Plant scientists use sophisticated molecular techniques to study the genetic basis of various aspects of plant growth and development, including leaf form. Many of the genes under study code for transcription factors. As discussed in Chapter 14, *transcription factors* are DNA-binding proteins that regulate the synthesis of RNA from a DNA template. An exciting example of this type of research is described in FIGURE 34-3. Eventually, such research will help plant biologists to understand the roles of all genes involved in plant development, an important goal of systems biology.

Leaf structure is adapted for maximum light absorption

The leaf is a complex organ composed of several tissues organized to optimize photosynthesis (FIG. 34-4). The leaf blade has upper and lower surfaces, each consisting of a layer of **epidermis**. The *upper epidermis* covers the upper surface, and the *lower epidermis* covers the lower surface. Most cells in these layers lack chloroplasts and are relatively transparent. One interesting feature of leaf epidermal cells is that the cell wall facing toward the outside environment is somewhat thicker than the cell wall facing inward. This extra thickness may provide the plant with additional protection against injury or water loss.

Because leaves have such a large surface area exposed to the atmosphere, water loss by evaporation from the leaf's surface is unavoidable. However, epidermal cells secrete a waxy layer, the **cuticle**, that reduces water loss from their exterior walls (see Table 33-4). The cuticle, which consists primarily

¹ Recall that flowering plants, the focus of this chapter, are divided into two main groups, informally called *eudicots* and *monocots* (see Chapter 28). Examples of eudicots include beans, petunias, oaks, cherry trees, roses, and snapdragons; monocots include corn, lilies, grasses, palms, tulips, orchids, and bananas.

(a) Leaf form: simple and compound.

(b) Leaf arrangement on a stem.

(c) Venation patterns.

Figure 34-2 Leaf morphology

All leaves shown are woody eudicot trees from North America, except Bermuda grass, which is a herbaceous monocot native to Europe and Asia.

of the waxy substance *cutin*, varies in thickness in different plants, in part as a result of environmental conditions. As one might expect, the leaves of plants adapted to hot, dry climates have extremely thick cuticles. Furthermore, a leaf's exposed (and warmer) upper epidermis generally has a thicker cuticle than its shaded (and cooler) lower epidermis.

The epidermis of many leaves is covered with various hair-like structures called **trichomes**, which have several functions (see Table 33-4). Trichomes of some plants help reduce water loss from the leaf surface by retaining a layer of moist air next to the leaf and by reflecting sunlight, thereby protecting the plant from

overheating. Some trichomes secrete stinging irritants for deterring *herbivores*, animals that feed on plants. In addition, a leaf covered with trichomes is difficult for an insect to walk over or eat. Other trichomes excrete excess salts absorbed from a salty soil.

The leaf epidermis contains minute openings, or **stomata** (sing., *stoma*), for gas exchange between leaf cells and the environment; the stomata are evenly spaced to optimize this gas exchange. Each stoma is flanked by two specialized epidermal **guard cells**, which are responsible for opening and closing the stoma (FIG. 34-5). Guard cells are usually the only epidermal cells with chloroplasts.

Stomata are especially numerous on the lower epidermis of horizontally oriented leaves (an average of about 100 stomata per square millimeter) and in many species are located *only* on the lower surface. The lower epidermis of apple (*Malus sylvestris*)

What molecular controls determine if a developing leaf will become simple or compound?

EXPERIMENT: *NAM/CUC* (No Apical Meristem/Cup-Shaped Cotyledon) genes were cloned and genetically manipulated in four distantly related flowering plants that normally produce compound leaves: *Aquilegia caerulea* (columbine), *Solanum lycopersicum* (tomato), *Cardamine hirsuta* (hairy bittercress), and *Pisum sativum* (garden pea). *NAM/CUC* genes were already known to code for plant transcription factors involved in the establishment and function of the shoot apical meristem.

RESULTS AND CONCLUSION: European scientists Thomas Blein, Patrick Laufs, and colleagues reported that the *timing* of gene silencing of *NAM/CUC* genes had the potential to produce less elaborate, simpler leaf structures. If a young leaf at the shoot apical meristem of a columbine plant had already developed deeply lobed leaflets, silencing the *NAM/CUC* genes would not affect its further development (leaf 1). The leaf margins of leaves 2 and 3 developed with fewer lobes because the *NAM/CUC* genes had been silenced before much leaf development had taken place. In leaf 4, very early silencing resulted in a simple leaf with an entire margin. Similar leaf simplifications occurred due to the timing of silencing of the *NAM/CUC* genes in the developing leaves of tomato, hairy bittercress, and garden pea.

Figure 34-3 Molecular controls and the development of leaf form

CONNECT Studies by other researchers have provided evidence that genes other than the ones described here also influence leaf form. Based on what you have learned in Chapters 14 and 17, would you expect them all to code for transcription factors? Explain your answer.

leaves, for example, has almost 400 stomata per square millimeter, whereas the upper epidermis has none. This adaptation reduces water loss because stomata on the lower epidermis are shielded from direct sunlight and are therefore cooler than those on the upper epidermis. In contrast, floating leaves of aquatic plants, such as water lilies, have stomata only on the upper epidermis.

Guard cells are associated with special epidermal cells called **subsidiary cells** that are often structurally different from other epidermal cells. Subsidiary cells provide a reservoir

Figure 34-4 The three plant tissue systems in a typical leaf blade

The dermal tissue system is represented by the upper epidermis and lower epidermis, which cover the blade. The photosynthetic ground tissue, called *mesophyll*, is often arranged into palisade and spongy layers. The vascular tissue system is represented by the xylem and phloem in the veins, which branch throughout the mesophyll.

Figure 34-5 Stoma

of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing (discussed later in this chapter).

Figure 34-6 Bundle sheath extension

LM of a wheat (*Triticum aestivum*) midvein in cross section. Note the bundle sheath extensions to both the upper epidermis and lower epidermis.

The photosynthetic ground tissue of the leaf, called the **mesophyll** (from the Greek *meso*, “the middle of,” and *phyll*, “leaf”), is sandwiched between the upper epidermis and the lower epidermis. Mesophyll cells, which are parenchyma cells (see Chapter 33) packed with chloroplasts, are loosely arranged, with many air spaces between them that facilitate gas exchange. These intercellular air spaces account for as much as 70% of the leaf’s volume.

In many plants the mesophyll is divided into two sublayers. Toward the upper epidermis, the columnar cells are stacked closely together in a layer called **palisade mesophyll**. In the lower portion, the cells are more loosely and irregularly arranged in a layer called **spongy mesophyll**. The two layers have different functions. Palisade mesophyll is specialized for light capture and is the main site of photosynthesis in the leaf. Photosynthesis also occurs in the spongy mesophyll, but the primary function of the spongy mesophyll is to allow diffusion of gases, particularly CO₂, within the leaf.

Palisade mesophyll may be organized into one, two, three, or even more layers of cells. The presence of additional layers is at least partly an adaptation to environmental conditions. Leaves exposed to direct sunlight contain more layers of palisade mesophyll than do shaded leaves on the same plant. In direct sunlight the light is strong enough to effectively penetrate multiple layers of palisade mesophyll, allowing all layers to photosynthesize efficiently.

The veins, or *vascular bundles*, of a leaf extend through the mesophyll. Branching is extensive, and no mesophyll cell is more than two or three cells away from a vein. Therefore, the slow process of diffusion does not limit the movement of needed resources between mesophyll cells and veins. Each vein contains two types of vascular tissue: xylem and phloem. **Xylem**, which conducts water and dissolved minerals (inorganic nutrients), is usually located in the upper part of a vein, toward the upper epidermis. **Phloem**, which conducts dissolved sugars, is usually confined to the lower part of a vein.

One or more layers of nonvascular cells surround the larger veins and make up the **bundle sheath**. Bundle sheaths are composed of parenchyma or sclerenchyma cells (see Chapter 33). Frequently, the bundle sheath has support columns, called **bundle sheath extensions**, that extend through the mesophyll from the upper epidermis to the lower epidermis (FIG. 34-6). Bundle sheath extensions may be composed of parenchyma, collenchyma, or sclerenchyma cells.

(a) **Eudicot leaf.** LM of part of a leaf cross section of privet (*Ligustrum vulgare*). The mesophyll has distinct palisade and spongy sections.

(b) **Monocot leaf.** LM of part of a leaf cross section of corn (*Zea mays*). Corn leaves lack distinct regions of palisade and spongy mesophyll.

Figure 34-7 Eudicot and monocot leaf cross sections

Leaf structure differs in eudicots and monocots Each eudicot leaf is usually composed of a broad, flattened blade and a petiole. As mentioned previously, eudicot leaves typically have netted venation. In contrast, many monocot leaves lack a petiole; they are narrow, and the base of the leaf often wraps around the stem to form a sheath. Parallel venation is characteristic of monocot leaves.

Eudicots and certain monocots also differ in internal leaf anatomy (FIG. 34-7). Although most eudicots and monocots have both palisade and spongy layers, some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers. Because eudicots have netted

veins, a cross section of a eudicot blade often shows veins in both cross-sectional and lengthwise views. In a cross section of a monocot leaf, in contrast, the parallel venation pattern produces evenly spaced veins, which all appear in cross section.

Differences between the guard cells in eudicot and certain monocot leaves also occur (FIG. 34-8). The guard cells of eudicots and many monocots are shaped like kidney beans. Other monocot leaves (those of grasses, reeds, and sedges) have guard cells shaped like dumbbells. These structural differences affect how the cells swell or shrink to open or close the stoma.

Leaf structure is related to function

How is leaf structure related to its primary function of photosynthesis? The epidermis of a leaf is relatively transparent and allows light to penetrate to the interior of the leaf where the photosynthetic ground tissue, the mesophyll, is located. Stomata, which dot the leaf surfaces, permit the exchange of gases between the atmosphere and the leaf's internal tissues. CO_2 , a raw material of photosynthesis, diffuses into the leaf through stomata, and the oxygen produced during photosynthesis diffuses rapidly out of the leaf through stomata. Other gases, including air pollutants, also enter the leaf's interior via stomata.

Water required for photosynthesis is obtained from the soil and transported in the xylem to the leaf, where it diffuses into the mesophyll and moistens the surfaces of mesophyll cells. The loose arrangement of the mesophyll cells, with air spaces between cells, allows for rapid diffusion of CO_2 to the mesophyll cell surfaces; there it dissolves in a film of water before diffusing into the cells.

The veins not only supply the photosynthetic ground tissue with water and minerals (from the roots, by way of the xylem) but also carry (in the phloem) dissolved sugar produced during photosynthesis to all parts of the plant. Bundle sheaths and bundle sheath extensions associated with the veins provide additional support to prevent the leaf, which is structurally weak because of the large amount of air space in the mesophyll, from collapsing under its own weight.

Leaves are adapted to help a plant survive in its environment Leaf structure reflects the environment to which a particular plant is adapted. Although both aquatic plants and those adapted to dry conditions perform photosynthesis and have the same basic leaf anatomy, their leaves are modified to

(a) Guard cells of eudicots and many monocots are bean-shaped.

(b) Some monocot guard cells are narrow in the center and thicker at each end.

Figure 34-8 Variation in guard cells

Guard cells are associated with epidermal cells called subsidiary cells.

enable them to survive different environmental conditions. The leaves of water lilies have petioles long enough to allow the blade to float on the water's surface. Large air spaces in the mesophyll make the floating blade buoyant. The petioles and other submerged parts have an internal system of air ducts; oxygen moves through these ducts from the floating leaves to the underwater roots and stems, which live in a poorly aerated environment.

Conifers are an important group of woody trees and shrubs that includes pine, spruce, fir, redwood, and cedar.² Most conifers are evergreen, which means that they lose leaves throughout the year rather than during certain seasons. Conifers dominate a large portion of Earth's land area, particularly in northern forests and mountains. The leaves of most conifers are waxy needles. Their needles have structural adaptations that help them survive winter, the driest part of the year. (Winter is arid even in areas of heavy snows because roots cannot absorb water from soil when the soil temperature is very low.) Indeed, many of the structural features of needles are also found in many desert plants.

FIGURE 34-9 shows a cross section of a pine needle. Note that the needle is somewhat thickened rather than thin and blade-like. The needle's relative thickness, which results in less surface area exposed to the air, reduces water loss. Other features that help conserve water include the thick, waxy cuticle and sunken stomata; these permit gas exchange while minimizing water loss. Thus, needles help conifers tolerate the dry winds that occur during winter (*dry* refers here to low relative humidity). With the warming of spring, soil water again becomes available, and the needles quickly resume photosynthesis.

² As discussed in Chapter 28, conifers are gymnosperms, one of the two groups of seed plants (the other group is the flowering plants, or angiosperms). Unlike flowering plants, whose seeds are enclosed in fruits, conifers bear "naked" seeds on the scales of female cones.

Figure 34-9 LM of a pine needle in cross section

The thick, waxy cuticle and sunken stomata are two structural adaptations that enable pine (*Pinus*) to retain its needles throughout the winter.

CHECKPOINT 34.1

- How are leaves adapted to conserve water?
- What is the photosynthetic ground tissue of a leaf called? What are its two sublayers?
- What are the two types of vascular tissue in a vascular bundle? Which vascular tissue is usually located in the upper part of the vascular bundle?
- How is the leaf organized to deliver the raw materials and remove the products of photosynthesis?

34.2 Stomatal Opening and Closing

LEARNING OBJECTIVES

- 5 Explain the role of blue light in the opening of stomata.
- 6 Outline the physiological changes that accompany stomatal opening and closing.

Stomata are adjustable pores that are usually open during the day when CO_2 is required for photosynthesis and closed at night when photosynthesis is shut down (see the section on CAM photosynthesis in Chapter 9 for an interesting exception). The opening and closing of stomata are controlled by changes in the shape of the two guard cells that surround each pore. The guard cells' shape is determined by their rigidity. When water moves into guard cells from surrounding non-guard cells, the guard cells become turgid (swollen) and bend, producing a pore. When water leaves the guard cells, they become flaccid (limp) and collapse against one another, closing the pore. What causes water to move into and out of guard cells?

Blue light triggers stomatal opening

Data from numerous experiments and observations are beginning to explain the complexities of stomatal movements. Let us begin with stomatal opening, which occurs when the plant detects light from the rising sun. You already know that light is a form of energy; plants absorb light and convert it to chemical energy in the process of photosynthesis. However, light is also an important *environmental signal* for plants; that is, light provides plants with information about their environment that they use to modify various activities at the molecular and cellular levels.

In stomatal opening and several other plant responses, *blue light*, which has wavelengths from 400 to 500 nm, is an environmental signal. Any plant response to light must involve a **pigment**, a molecule that absorbs the light, before the induction of a particular biological response. Data such as the responses of stomata to different colors of light suggest that the pigment involved in stomatal opening and closing

is yellow (yellow pigments strongly absorb blue light). The yellow pigment is thought to be located in the guard cells, probably in their plasma membranes.

In **FIGURE 34-10**, blue light, which is a component of sunlight, triggers the activation of proton pumps, located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the hydrolysis (splitting) of starch (discussed later).

The proton pumps use ATP energy to actively transport protons (H^+) out of the guard cells. The H^+ that are pumped are formed when malic acid produced in the guard cells ionizes to form H^+ and negatively charged malate ions. As the proton pumps in the plasma membranes of guard cells transport protons out of the guard cells, an **electrochemical gradient**—that is, a charge and concentration difference—forms across the guard cell plasma membrane.

The resulting electrochemical gradient of H^+ drives the facilitated diffusion of large numbers of potassium ions *into* guard cells. This movement occurs through **voltage-activated ion channels**, which are specific for potassium ions and open when a certain voltage (difference in charge between the two sides of the guard cell plasma membrane) is attained. This movement of potassium ions has been experimentally measured by the **patch clamp technique**, in which researchers seal the tip of a micropipette to a tiny patch of membrane that contains a single ion channel. As illustrated in Figure 41-5, these scientists then measure the flow of ions through that channel between the cytoplasm and the solution in the micropipette. (Interestingly, in animals, voltage-activated ion channels are found in the plasma membranes of nerve cells and are involved in transmitting neural impulses.)

Chloride ions are also taken into the guard cells through ion channels in the guard cell plasma membrane. The negatively charged chloride and malate ions help electrically balance the positively charged potassium ions.

The potassium, chloride, and malate ions accumulate in the vacuoles of the guard cells, thus increasing the solute concentration in the vacuoles. You may recall from the discussion of osmosis in Chapter 5 that when a cell has a solute concentration greater than that of surrounding cells, water flows *into* the cell. Thus, water enters the guard cells from surrounding epidermal cells by osmosis. The increased turgidity of the guard cells changes their shape because the thickened inner cell walls do not expand as much as the outer walls, and so the stoma opens.

blue light activates proton pumps → proton pumps move H^+ out of guard cells → K^+ and Cl^- diffuse into guard cells through voltage-activated ion channels → water diffuses by osmosis into guard cells → guard cells change shape and stoma opens

Stomata close in the late afternoon or early evening, but not by an exact reversal of the opening process. Recent studies have demonstrated that the concentration of potassium ions in guard cells slowly decreases during the day.

Key Point

The accumulation of osmotically active ions (K^+ and Cl^-) in the guard cells is driven by a proton (H^+) gradient.

Figure 34-10 Mechanism of stomatal opening

CONNECT Guard cells are usually the only epidermal cells that are photosynthetic. How does that feature relate to the mechanisms of stomatal opening and closing?

However, the concentration of sucrose, another osmotically active substance, increases during the day—maintaining the open pore—and then slowly decreases as evening approaches. This sucrose comes from the hydrolysis of the polysaccharide starch, which is stored in the guard cell chloroplasts. As evening approaches, the sucrose concentration in the guard cells declines as sucrose is converted back to starch (which is osmotically inactive), water leaves by osmosis, the guard cells lose their turgidity, and the pore closes.

To summarize, different mechanisms appear to regulate the opening and closing of stomata. The uptake of potassium and chloride ions is mainly associated with stomatal opening, and the declining concentration of sucrose is mainly associated with stomatal closing. In Chapter 38 we discuss other blue-light responses in plants.

Additional factors affect stomatal opening and closing

Although light and darkness trigger the opening and closing of stomata, other environmental factors are also involved, including CO_2 concentration. A low concentration of CO_2 in the leaf induces stomata to open, even in the dark. The effects of light and CO_2 concentration on stomatal opening are interrelated. Photosynthesis, which occurs in the presence of light, reduces the internal concentration of CO_2 in the leaf, triggering stomatal opening. Another environmental factor that affects stomatal opening and closing is water stress. During a prolonged drought, stomata remain closed, even during the day. Stomatal opening and closing are under hormonal control, particularly by the plant hormone *abscisic acid* (see Table 38-1).

The opening and closing of stomata are also regulated by an internal biological clock that in some way measures time. For example, after plants are placed in continual darkness, their stomata continue to open and close at more or less the same time each day. Such biological rhythms that follow an approximate 24-hour cycle are known as **circadian rhythms**. Other examples of circadian rhythms are provided in Chapter 38.

CHECKPOINT 34.2

- How does blue light trigger stomatal opening?
- What physiological changes occur in guard cells during stomatal opening? during stomatal closing?

34.3 Transpiration and Guttation

LEARNING OBJECTIVES

- 7 Discuss transpiration and its effects on plants.
- 8 Distinguish between transpiration and guttation.

Despite leaf adaptations such as the cuticle, approximately 99% of the water that a plant absorbs from the soil is lost by evaporation from the leaves and, to a lesser extent, the stems. Loss of water vapor by evaporation from aerial plant parts is called **transpiration**.

The cuticle is extremely effective in reducing water loss by transpiration. It is estimated that only 1% to 3% of the water lost from a plant passes directly through the cuticle. Most transpiration occurs through open stomata. The numerous stomatal pores that are so effective in gas exchange for photosynthesis also provide openings through which water vapor escapes. In addition, the loose arrangement of the spongy mesophyll cells provides a large surface area within the leaf from which water can evaporate.

Several environmental factors influence the rate of transpiration. More water is lost from plant surfaces at higher temperatures than at lower temperatures. Light increases the transpiration rate, in part because it triggers stomatal opening and in part because it increases the leaf's temperature. Wind and dry air increase transpiration, but humid air *decreases* transpiration because the air is already saturated, or nearly so, with water vapor.

Although transpiration may seem wasteful, particularly to farmers in arid lands, it is an essential process that has adaptive value.

Transpiration is responsible for water movement in plants, and without it water would not reach the leaves from the soil (see discussion of the tension–cohesion model in Chapter 35). The large amount of water that plants lose by transpiration may provide some additional benefits. Transpiration, like sweating in humans, cools the leaves and stems. When water passes from a liquid state to a vapor, it absorbs a great deal of heat. When the water molecules leave the plant as water vapor, they carry this heat with them. Thus, the cooling effect of transpiration may prevent leaves from overheating, particularly in direct sunlight.

Another benefit of transpiration is that it distributes essential minerals throughout the plant. The water that a plant transpires is initially absorbed from the soil, where it is present not as pure water but as a dilute solution of dissolved mineral salts. The water and dissolved minerals are then transported in the xylem throughout the plant, including its leaves. Water moves from the plant to the atmosphere during transpiration, but minerals remain in plant tissues. Many of these minerals are required for the plant's growth. It has been suggested that transpiration enables a plant to take in sufficient water to provide enough essential minerals; it has also been suggested that plants cannot satisfy their mineral requirements if the transpiration rate is not high enough.

There is no doubt, however, that under certain circumstances excessive transpiration can be harmful to a plant. On hot summer days, plants frequently lose more water by transpiration than they can take in from the soil. Their cells experience a loss of turgor, and the plants wilt (FIG. 34-11). If a plant is able to recover overnight because of the combination of negligible transpiration (recall that stomata are

(a) In the late afternoon of a hot day, the leaves have wilted because of water loss. Note that wilting helps reduce the surface area from which transpiration occurs.

(b) The next morning, water in the leaves has been replenished. Transpiration is negligible during the night, and the plants recover by absorbing water from the soil.

Figure 34-11 Temporary wilting in squash (*Cucurbita pepo*) leaves

closed) and absorption of water from the soil, the plant is said to have experienced *temporary wilting*. Most plants recover from temporary wilting with no ill effects. In cases of prolonged drought, however, the soil may not contain sufficient moisture to permit recovery from wilting. A plant that cannot recover is said to be *permanently wilted* and will die.

Transpiration is an important part of the **hydrologic cycle**, in which water cycles from the ocean and land to the atmosphere and then back to the ocean and land (see Fig. 55-11). As a result of transpiration, water evaporates from leaves and stems to form clouds in the atmosphere. Thus, transpiration eventually results in precipitation. As you may expect, forest trees release substantial amounts of moisture into the air by transpiration. Researchers have determined that at least half the rain that falls in the Amazon rainforest basin is recycled again and again by transpiration and precipitation.

Some plants exude liquid water

Many leaves have special structures at vein endings through which liquid water is literally forced out. This loss of liquid water, known as **guttation**, occurs when transpiration is negligible and available soil moisture is high. Guttation typically occurs in low-growing plants at night because the stomata are closed, but water continues to move into the roots by osmosis. People sometimes mistake the early morning water droplets formed on leaf margins by guttation for dew (FIG. 34-12). Unlike dew, which condenses from cool night air, guttation droplets come from within the plant. (The mechanism for guttation is discussed in Chapter 35.)

Figure 34-12 Guttation

Shown is a compound leaf of strawberry (*Fragaria*) with water droplets formed by guttation.

CHECKPOINT 34.3

- **CONNECT** How is leaf structure related to transpiration?
- How do environmental factors (sunlight, temperature, humidity, and wind) influence the rate of transpiration?
- **CONNECT** In what ways is transpiration detrimental to plants? What are its benefits?
- How does guttation differ from transpiration?

34.4 Leaf Abscission

LEARNING OBJECTIVE

- 9 Define leaf *abscission*, explain why it occurs, and describe the physiological and anatomical changes that precede it.

All trees shed leaves, a process known as **abscission**. Many conifers shed their needles in small numbers year-round. The leaves of deciduous plants turn color and abscise, or fall off, once a year as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with pronounced wet and dry seasons. In temperate forests, most

woody plants with broad leaves shed their leaves to survive the low temperatures of winter. During winter, the plant's metabolism, including its photosynthetic machinery, slows down or halts temporarily.

Another reason for abscission is related to a plant's water requirements, which become critical during the physiological drought of winter. As mentioned previously, as the ground chills, absorption of water by the roots is inhibited. When the ground freezes, *no* absorption occurs. If the broad leaves were to stay on the plant during the winter, the plant would continue to lose water by transpiration but would be unable to replace it with water absorbed from the soil.

Leaf abscission is a complex process that involves many physiological changes, all initiated and orchestrated by changing levels of plant hormones, particularly *ethylene*. Briefly, the process is as follows. As autumn approaches, sugars, amino acids, and many essential minerals (such as nitrogen, phosphorus, and possibly potassium) are mobilized and transported from the leaves to other plant parts; these minerals will be reused during the following spring. Chlorophyll breaks down, allowing the **carotenoids** (orange carotenes and yellow xanthophylls), some of the accessory pigments in the chloroplasts of leaf cells, to become evident (see Fig. 3-14b). Accessory pigments are always present in the chloroplasts but are masked by the green of the chlorophyll. In addition, red water-soluble pigments called **anthocyanins** may accumulate in the vacuoles of epidermal leaf cells in some species; anthocyanins may protect leaves against damage by ultraviolet radiation. The various combinations of carotenoids and anthocyanins are responsible for the brilliant colors found in autumn landscapes in temperate climates.

In many leaves, abscission occurs at an abscission zone near the base of the petiole

The area where a petiole detaches from the stem is a structurally distinct area called the **abscission zone**. Composed primarily of thin-walled parenchyma cells, it is anatomically weak because it contains few fibers (**FIG. 34-13**). A protective layer of cork cells develops on the stem side of the abscission zone. These cells have a waxy, waterproof material impregnated in their walls. Enzymes then dissolve the **middle lamella** (the “cement” that holds the primary cell walls of adjacent cells together) in the abscission zone (see Fig. 4-30). Once this process is completed, nothing holds the leaf to the stem but a few xylem cells. A sudden breeze is enough to make the final break, and the leaf detaches. The protective layer of cork remains, sealing off the area and forming a leaf scar.

Although the structure of abscission zones and the physiological changes associated with abscission have been well known for many years, only recently have botanists investigated the genes responsible for the development of an abscission zone and the physiological changes of leaf abscission. Using **DNA microarrays**, for example, botanists have identified about 35 genes that are expressed in leaves only as winter approaches.

Figure 34-13 Abscission zone

This LM of a longitudinal section through a silver maple (*Acer saccharinum*) branch shows the abscission zone at the base of a petiole. An axillary bud with its protective bud scales is also evident above the petiole.

As discussed in Chapter 15, a DNA microarray contains hundreds of different DNA molecules placed on a glass slide or chip. Some of the genes identified in these studies code for degradative enzymes involved in breaking down proteins and other molecules; others have functions not yet identified.

CHECKPOINT 34.4

- Why do many woody plants living in temperate zones lose their leaves in autumn?
- What physiological changes occur during leaf abscission?
- What is the abscission zone?

34.5 Modified Leaves

LEARNING OBJECTIVE

- 10** List at least four examples of modified leaves and give the function of each.

Although photosynthesis is the main function of leaves, certain leaves have special modifications for other functions. Some plants have leaves specialized for deterring herbivores. **Spines**, modified leaves that are hard and pointed, are found on many desert plants, such as cacti (FIG. 34-14a). In the cactus, the main

organ of photosynthesis is the stem rather than the leaf. Spines discourage animals from eating the succulent stem tissue.

Vines are climbing plants whose stems cannot support their own weight, so they often possess **tendrils** that help keep the vine attached to the structure on which it is growing. The tendrils of many vines, such as peas, cucumbers, squash, and sweet peas, are specialized leaves (FIG. 34-14b). However, some tendrils, such as those of ivy, Virginia creeper, and grape, are specialized stems.

The winter buds of a dormant woody plant are covered by **bud scales**. These modified leaves protect the delicate meristematic tissue of the bud from injury, freezing, or drying out (FIG. 34-14c).

Some leaves associated with flower clusters (inflorescences) are modified as **bracts**. In flowering dogwood, the inconspicuous flowers are clustered in the center of each inflorescence, and what appears to be four white or pink petals are actually bracts. Similarly, the red “petals” of poinsettia are not petals at all but bracts (FIG. 34-14d).

Leaves may also be modified for storage of water or food. For example, a **bulb** is a short, underground stem to which large, fleshy leaves are attached (FIG. 34-14e). Onions and tulips form bulbs. Many plants adapted to arid conditions, such as jade plants, medicinal aloes, and string-of-beads, have succulent leaves for water storage (FIG. 34-14f). These leaves are usually green and function in photosynthesis.

Some leaves are modified for either sexual reproduction (see discussion of flower evolution in Chapter 28, including Figure 28-15) or asexual reproduction (see Fig. 37-17).

(f) The succulent leaves of the string-of-beads plant (*Senecio rowleyanus*) are spherical to minimize surface area, thereby conserving water.

Figure 34-14 Leaf modifications

Modified leaves of carnivorous plants capture insects

Carnivorous plants are plants that capture insects. Most carnivorous plants grow in poor soil that is deficient in certain essential minerals, particularly nitrogen. These plants meet some of their mineral requirements by digesting insects and other small animals. The leaves of carnivorous plants are adapted to attract, capture, and digest their animal prey.

Some carnivorous plants have passive traps. The leaves of a pitcher plant, for example, are shaped so that rainwater collects and forms a reservoir that also contains acid secreted by the plant (**FIG. 34-15**). Some pitchers are quite large; in the tropics, pitcher plants may be large enough to hold 1L (approximately 1 qt) or more of liquid. An insect attracted by the odor or nectar of the pitcher may lean over the edge and fall in. Although it may make repeated attempts to escape, the insect is prevented from crawling out by the slippery sides and the rows of stiff hairs that point downward around the lip of the pitcher. The insect eventually drowns, and part of its body disintegrates and is absorbed.

Most insects are killed in pitcher plants. However, the larvae of several insects (certain flies, midges, and mosquitoes) and a large community of microorganisms live inside the pitchers. These insect species obtain their food from the insect carcasses, and the pitcher plant digests what remains. It is not known how these insects survive the acidic environment inside the pitcher.

The Venus flytrap is a carnivorous plant with active traps. Its leaf blades resemble tiny bear traps (see Fig. 1-3). Each side of the leaf blade contains three small, stiff hairs. If an insect alights and brushes against two of the hairs or against the same hair twice in quick succession, the trap springs shut with amazing rapidity, about 100 milliseconds. The spines along the margins of the blades fit closely together to prevent the insect from escaping. After the leaf initially traps the insect, the leaf continues to slowly close for the next several hours. Digestive glands on the surface of the trap secrete enzymes in response to the insect pressing against them. Days later, after the insect has died and been digested, the trap reopens and the indigestible remains fall out.

Marvin Dembinsky Photo Associates/Alamy Stock Photo

Figure 34-15 A common pitcher plant

This species (*Sarracenia purpurea*), whose pitchers grow to 30.5 cm (12 in.), is widely distributed in acidic bogs and marshes in eastern North America. Young pitchers are green but turn red as they age. Note the dead beetle in the pitcher.

CHECKPOINT 34.5

- What are the primary functions of each of the following modified leaves: spines, tendrils, and bud scales?
- What are the functions of bulbs? of succulent leaves?
- What are some of the specialized features of the leaves of carnivorous plants?

Summary: Focus on Learning Objectives

34.1 Leaf Form and Structure (page 730)

- 1 **Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.**
 - Leaves may be simple (having a single **blade**) or compound (having a blade divided into two or more leaflets).
 - Leaf arrangement on a stem may be alternate (one leaf at each **node**), opposite (two leaves at each node), or whorled (three or more leaves at each node).
 - Leaves may have parallel or netted venation. Netted venation may be palmately netted, with several major **veins** radiating from one point, or pinnately netted, with veins branching along the entire length of the midvein.
- 2 **Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem) and sketch how they are arranged in a leaf cross section.**
 - Upper and lower surfaces of the leaf blade are covered by an **epidermis**. A waxy **cuticle** coats the epidermis, enabling the plant to survive the dry conditions of a terrestrial existence.
 - **Stomata** are small pores in the epidermis that permit gas exchange needed for photosynthesis. Each pore is surrounded by two **guard cells** that are often associated with special epidermal cells called **subsidiary cells**. Subsidiary cells provide a reservoir of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing.
 - **Mesophyll** consists of photosynthetic parenchyma cells. Mesophyll is divided into **palisade mesophyll**, which functions primarily for photosynthesis, and **spongy mesophyll**, which functions primarily for gas exchange.
 - Leaf veins have **xylem** to conduct water and essential minerals to the leaf and **phloem** to conduct sugar produced by photosynthesis to the rest of the plant.
- 3 **Compare leaf anatomy in eudicots and monocots.**
 - Monocot leaves have parallel venation, whereas eudicot leaves have netted venation. Some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers. Some monocots (grasses, reeds, and sedges) have guard cells shaped like dumbbells, unlike the more common bean-shaped guard cells.
- 4 **Relate leaf structure to its function of photosynthesis.**
 - Leaf structure is adapted for its primary function of **photosynthesis**. Most leaves have a broad, flattened blade that efficiently collects the sun's radiant energy. The transparent epidermis allows light to penetrate into the middle of the leaf, where photosynthesis occurs.
 - Stomata generally open during the day for gas exchange needed during photosynthesis and close at night to conserve water when photosynthesis is not occurring.
 - Air spaces in mesophyll tissue permit the rapid diffusion of CO₂ and water into, and oxygen out of, mesophyll cells.

34.2 Stomatal Opening and Closing (page 736)

- 5 **Explain the role of blue light in the opening of stomata.**
 - **Blue light**, which is a component of sunlight, triggers the activation of proton pumps located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the hydrolysis of starch.
- 6 **Outline the physiological changes that accompany stomatal opening and closing.**
 - Protons (H⁺), produced when malic acid ionizes, are pumped out of the guard cells. As protons leave the guard cells, an **electrochemical gradient** (a charge and concentration difference) forms on the two sides of the guard cell plasma membrane.
 - The electrochemical gradient drives the uptake of potassium ions (K⁺) through specific **voltage-activated ion channels** into the guard cells. Chloride ions (Cl⁻) are also taken into the guard cells through ion channels. These osmotically active ions increase the solute concentration in the guard cell vacuoles. The resulting osmotic movement of water into the guard cells causes them to become turgid, forming a pore.
 - As the day progresses, potassium ions slowly leave the guard cells, and starch is hydrolyzed to sucrose, an osmotically active solute, which increases in concentration in the guard cells. Stomata close when water leaves the guard cells as a result of a decline in the concentration of sucrose, which occurs as evening approaches. The sucrose is converted to starch, which is osmotically inactive.

34.3 Transpiration and Guttation (page 737)

- 7 **Discuss transpiration and its effects on plants.**
 - **Transpiration** is the loss of water vapor from aerial parts of plants. Transpiration, which occurs primarily through the stomata, is affected by environmental factors such as temperature, wind, and relative humidity.
 - Transpiration appears to be both beneficial and harmful to the plant; that is, transpiration represents a trade-off between the CO₂ requirement for photosynthesis and the need for water conservation.
- 8 **Distinguish between transpiration and guttation.**
 - **Guttation**, the release of liquid water from leaf margins of some plants, occurs through special structures when transpiration is negligible and available soil moisture is high. In contrast, transpiration is the loss of water vapor and occurs primarily through the stomata.

34.4 Leaf Abscission (page 739)

- 9 **Define leaf *abscission*, explain why it occurs, and describe the physiological and anatomical changes that precede it.**
 - Leaf **abscission** is the loss of leaves that often occurs as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with wet and dry seasons.
 - Abscission involves physiological and anatomical changes that occur prior to leaf fall. An **abscission zone** develops where the petiole detaches from the

stem. Sugars, amino acids, and many essential minerals are transported from the leaves to other plant parts. Chlorophyll breaks down, and **carotenoids** and **anthocyanins** become evident.

34.5 Modified Leaves (page 740)

10 List at least four examples of modified leaves and give the function of each.

- **Spines** are leaves adapted to deter herbivores. Some **tendrils** are leaves modified for grasping and holding on to other structures (to support weak stems). **Bud scales**

are leaves modified to protect delicate meristematic tissue or dormant buds. **Bracts** are modified leaves associated with some inflorescences. **Bulbs** are short, underground stems with fleshy leaves specialized for storage. Many plants adapted to arid conditions have succulent leaves for water storage. Carnivorous plants have leaves modified to trap insects.

Test Your Understanding

Know and Comprehend

1. Plants with an alternate leaf arrangement have (a) blades divided into two or more leaflets (b) major veins that radiate out from one point (c) one leaf at each node (d) major veins branching off along the entire length of the midvein (e) two leaves at each node
2. The primary function of the spongy mesophyll is (a) reducing water loss from the leaf surface (b) changing the shape of the guard cells (c) supporting the leaf to prevent it from collapsing under its own weight (d) diffusing gases within the leaf (e) deterring herbivores
3. Gas exchange occurs through microscopic pores formed by two (a) subsidiary cells (b) abscission cells (c) mesophyll cells (d) guard cells (e) stipules
4. The thin, noncellular layer of wax secreted by the epidermis of leaves is the (a) stoma (b) abscission zone (c) trichome (d) bundle sheath (e) cuticle
5. Which of the following is *not* an adaptation of pine needles to conserve water? (a) less surface area exposed to the air than thin-bladed leaves (b) a relatively thick cuticle (c) sunken stomata (d) netted veins instead of parallel veins (e) both c and d are not adaptations of pine needles
6. When transpiration is negligible, plants such as grasses exude excess water by (a) guttation (b) circadian rhythm (c) abscission (d) pumping H^+ out of and K^+ into guard cells (e) photosynthesis
7. At sunrise, the accumulation in the guard cells of the osmotically active substance _____ causes an inflow of water and the opening of the pore. (a) protons (b) starch (c) ATP synthase (d) sucrose (e) potassium ions
8. Stomatal opening is most pronounced in response to _____ light. (a) green (b) yellow (c) blue (d) ultraviolet (e) infrared
9. Anatomically, the abscission zone where a petiole detaches from a stem consists of (a) thin-walled parenchyma cells with few fibers (b) thick-walled cork parenchyma cells (c) clusters of fibers and collenchyma strands (d) hard, pointed stipules (e) epidermal cells with sunken stomata
10. Modified leaves that enable a stem to climb are called _____, whereas modified leaves that cover the winter buds of a dormant woody plant are called _____. (a) spines; bud scales (b) bud scales; tendrils (c) tendrils; bud scales (d) tendrils; spines (e) carnivorous leaves; spines

11. There is a trade-off between photosynthesis and transpiration in leaves because (a) numerous stomatal pores provide both gas exchange for photosynthesis and openings through which water vapor escapes (b) a waxy layer, the cuticle, reduces water loss (c) blue light triggers an influx of potassium ions (K^+) into the guard cells (d) leaves of deciduous plants abscise as winter approaches in temperate climates (e) stomata are closed at night, although water continues to move into the roots by osmosis

Apply and Analyze

12. Suppose that you are asked to observe a micrograph of a leaf cross section and distinguish between the upper and lower epidermis. How would you make this decision?
13. **CONNECT** Given that (a) xylem is located toward the upper epidermis in leaf veins and phloem is located toward the lower epidermis and (b) the vascular tissue of a leaf is continuous with that of the stem, suggest one possible arrangement of vascular tissues in the stem that might account for the arrangement of vascular tissue in the leaf.
14. **VISUALIZE** Draw a simple cross section of a leaf. Label the upper epidermis, lower epidermis, guard cells, spongy mesophyll, palisade mesophyll, and vascular tissue. Which cells contain chloroplasts?

Evaluate and Synthesize

15. What might be some of the advantages of a plant having a few large leaves? What might be some disadvantages? What might be some advantages of having many small leaves? What disadvantages might that entail? How would your answers differ for plants growing in a humid environment compared with those in a desert?
16. **EVOLUTION LINK** What is the selective advantage of seasonal leaf abscission in woody flowering plants living in colder climates? What adaptations enable conifers to survive these climates without leaf abscission?
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Briefly explain why research on the molecular mechanism of stomatal closure might be of future use in agriculture.

35 Stem Structure and Transport

A vegetative (not sexually reproductive) vascular plant has three parts: roots, leaves, and stems. As discussed in Chapter 33, roots serve to anchor the plant and absorb materials from the soil, whereas leaves are primarily for photosynthesis, converting radiant energy into the chemical energy of carbohydrate molecules. Stems, the focus of this chapter, link a plant's roots to its leaves and are usually located aboveground, although many plants have underground stems. Stems exhibit varied forms, ranging from ropelike vines to massive tree trunks (see photograph). They can be herbaceous, with soft, nonwoody tissues, or they can be woody, with extensive hard tissues of wood and bark.

Stems perform three main functions in plants. First, stems of most species support leaves and reproductive structures. The upright position of most stems and the arrangement of the leaves on them allow each leaf to absorb light for use in photosynthesis. Reproductive structures (such as flowers and fruits) are located on stems in areas accessible to insects, birds, and air currents, which transfer pollen from flower to flower and help disperse seeds and fruits.

Second, stems provide internal transport. They conduct water and dissolved minerals (inorganic nutrients) from the roots, where these materials are absorbed from the soil, to leaves and other plant parts. Stems also conduct the sugar produced in leaves by photosynthesis to roots and other parts of the plant. Remember, however, that stems are not the only plant organs that conduct materials. The vascular system is continuous throughout all parts of a plant, and conduction occurs in roots, stems, leaves, and reproductive structures.

KEY CONCEPTS

- 35.1** Primary tissues (epidermis, cortex, pith, xylem, and phloem) of stems develop from shoot apical meristems. Secondary tissues (wood and bark) of stems develop from two lateral meristems: vascular cambium and cork cambium.
- 35.2** The concept of water potential explains the direction of water transport into, through, and out of a plant. According to the tension–cohesion model, transpiration pulls water up through the stem as water evaporates from leaves by transpiration.
- 35.3** According to the pressure–flow model, sucrose is translocated in phloem sap from the source, where the sugar is loaded into phloem, to the sink, where the sugar is removed from phloem.

PHOTO: Giant sequoias. Giant sequoias (*Sequoiadendron giganteum*) are the most massive trees on Earth. Their huge stems grow to 75 m (250 ft) or more. Photographed in Sequoia National Park, California. Robert Harding World Imagery/Alamy Stock Photo

Third, stems produce new living tissue. They continue to grow throughout a plant's life, producing *buds* that develop into stems with new leaves and/or reproductive structures. In addition to the main functions of support, conduction, and production of new stem tissues, stems of some species are modified for asexual reproduction (see Chapter 37) or, if green, to manufacture sugar by photosynthesis.

35.1 Stem Growth and Structure

LEARNING OBJECTIVES

- 1 Sketch cross sections of herbaceous eudicot and monocot stems, and describe the functions of each tissue.
- 2 Name the two lateral meristems and describe the tissues that arise from each.
- 3 Outline the transition from primary growth to secondary growth in a woody stem.

You may recall from Chapter 33 that plants have two different types of growth. **Primary growth** is an increase in the length of a plant and occurs at **apical meristems** located at the tips of roots and shoots and also within the buds of stems. **Secondary growth** is an increase in the girth (thickness) of a plant as a result of the activity of **lateral meristems** located within stems and roots. The new tissues formed by the lateral meristems are called *secondary tissues* to distinguish them from *primary tissues* produced by apical meristems.

All plants have primary growth; some plants have both primary and secondary growth. Stems with only primary growth are herbaceous, whereas those with both primary and secondary growth are generally woody. (Certain herbaceous stems, such as geranium and sunflower, also have a limited amount of secondary growth.) A woody plant increases in length by primary growth at the tips of its stems and roots, whereas its older stems and roots farther back from the tips increase in girth by secondary growth. In other words, at the same time that primary growth is increasing the length of the stem, secondary growth is adding wood and bark, thereby causing the stem to thicken.

Herbaceous eudicot and monocot stems differ in internal structure

Although considerable structural variation exists in stems, they all possess an outer protective covering (epidermis or periderm), one or more types of ground tissue, and vascular tissues (xylem and phloem). Let us first consider the structure of herbaceous eudicot stems and then the structure of monocot stems.

Vascular bundles of herbaceous eudicot stems are arranged in a circle in cross section A young sunflower stem is a representative herbaceous eudicot stem that exhibits primary growth (FIG. 35-1). Its outer covering, the **epidermis**, provides protection in herbaceous stems, as it does in leaves and herbaceous roots (see Table 33-4 and Fig. 33-5). The **cuticle**, a waxy layer of *cutin*, covers the stem epidermis and reduces water loss from the stem surface. **Stomata** permit gas exchange. (Recall from Chapter 34 that a cuticle and stomata are also associated with the leaf epidermis.)

(a) Cross section of a sunflower (*Helianthus annuus*) stem. Note the vascular bundles arranged in a circle around a central core of pith.

(b) Close-up of a vascular bundle. In each bundle, xylem is located toward the stem's interior, and phloem toward the exterior. Each vascular bundle is "capped" by a batch of fibers for additional support.

Figure 35-1 LMs of a herbaceous eudicot stem

Inside the epidermis is the **cortex**, a cylinder of ground tissue that may contain parenchyma, collenchyma, and sclerenchyma cells (see Table 33-2 and Fig. 33-3). As might be expected from the various types of cells that it contains, the cortex in herbaceous eudicot stems can have several functions, such as photosynthesis, storage, and support. If a stem is green, photosynthesis occurs in chloroplasts of cortical parenchyma cells. Parenchyma in the cortex also stores starch (in amyloplasts) and crystals (in vacuoles). Collenchyma and sclerenchyma in the cortex confer strength and structural support for the stem.

The vascular tissues provide conduction and support. In herbaceous eudicot stems, the vascular tissues are located in bundles that, when viewed in cross section, are arranged in a circle. However, viewed lengthwise, these bundles extend as long strands throughout the length of a stem and are continuous with vascular tissues of both roots and leaves.

Each vascular bundle contains both **xylem**, which transports water and dissolved minerals from roots to leaves, and **phloem**, which transports dissolved sugar (see Table 33-3 and Fig. 33-4). Xylem is located on the inner side of the vascular bundle, and phloem is found toward the outside. Sandwiched between xylem and phloem in some herbaceous stems is a single layer of cells called the *vascular cambium*, a lateral meristem responsible for secondary growth (discussed later).

Because most stems support the aerial plant body, they are much stronger than roots. The thick walls of tracheids

and vessel elements in xylem help support the plant. Fibers also occur in both xylem and phloem, although they are usually more extensive in phloem. These fibers add considerable strength to the herbaceous stem. In sunflowers and certain other herbaceous eudicot stems, phloem contains a cluster of fibers toward the outside of the vascular bundle, called a *phloem fiber cap*, that helps strengthen the stem. The phloem fiber cap is not present in all herbaceous eudicot stems.

The **pith** is a ground tissue at the center of the herbaceous eudicot stem that consists of large, thin-walled parenchyma cells that function primarily in storage. Because of the arrangement of the vascular tissues in bundles, there is no distinct separation of cortex and pith between the vascular bundles. The areas of parenchyma between the vascular bundles are often referred to as *pith rays*.

Vascular bundles are scattered throughout monocot stems

An epidermis with its waxy cuticle covers monocot stems, such as the herbaceous stem of corn. As in herbaceous eudicot stems, the vascular tissues run in strands throughout the length of a stem. In cross section the vascular bundles contain xylem toward the inside and phloem toward the outside. In contrast with herbaceous eudicots, however, vascular bundles of monocots are not arranged in a circle but are scattered throughout the stem (**FIG. 35-2**). Each vascular bundle is enclosed in a bundle sheath of supporting sclerenchyma cells. The monocot stem does not have distinct areas of cortex

Figure 35-2 LMs of a monocot stem

and pith. The ground tissue in which the vascular tissues are embedded performs the same functions as cortex and pith in herbaceous eudicot stems.

Monocot stems do not possess lateral meristems (vascular cambium and cork cambium) that give rise to secondary growth. Monocots have primary growth only and do not produce wood and bark. Although some tree-like monocots (such as palms) attain considerable size, they do so by a modified form of primary growth in which parenchyma cells divide and enlarge. Stems of some monocots (such as bamboo and palm) contain a great deal of sclerenchyma tissue, which makes them hard and woodlike in appearance.

Woody plants have stems with secondary growth

Woody plants undergo secondary growth, an increase in the girth of stems and roots. Secondary growth occurs as a result of the activity of two lateral meristems: vascular cambium and cork cambium. Among flowering plants, only woody eudicots (such as apple, hickory, and maple) have secondary growth. Cone-bearing gymnosperms (such as pine, juniper, and spruce) also have secondary growth.

Cells in the **vascular cambium** divide and produce two conducting and supporting tissues: secondary xylem (wood) to replace primary xylem and secondary phloem (inner bark) to replace primary phloem. Primary xylem and primary phloem are not able to transport materials indefinitely and so are replaced in plants that have extended lifespans.

Cells of the outer lateral meristem, called cork cambium, divide and produce cork cells and cork parenchyma. **Cork cambium** and the tissues it produces are collectively referred to as **periderm** (outer bark), which functions as a replacement for the epidermis (see the last LM in Table 33-4).

Vascular cambium gives rise to secondary xylem and secondary phloem Primary tissues in woody eudicot stems are organized like those in herbaceous eudicot stems, with the vascular cambium forming a thin layer of cells sandwiched between xylem and phloem in the vascular bundles. Once secondary growth begins, the internal structure of a stem changes considerably (**FIG. 35-3**). Although vascular cambium is not initially a continuous cylinder of cells (because the vascular bundles are separated by pith rays), it becomes continuous when production of secondary tissues begins. This continuity develops because certain parenchyma cells in each pith ray retain the ability to divide. These cells connect to vascular cambium cells in each vascular bundle, forming a complete ring of vascular cambium in cross section.

Cells in the vascular cambium divide and produce daughter cells in two directions. The cells formed from the dividing vascular cambium are located either *inside* the

ring of vascular cambium (to become secondary xylem, or wood) or *outside* it (to become secondary phloem, or inner bark) (**FIG. 35-4**). When a cell in the vascular cambium divides tangentially (inward or outward), one daughter cell remains meristematic; that is, it remains part of the vascular cambium. The other cell may divide again several times, but eventually it stops dividing and develops into mature secondary tissue. Thus, vascular cambium is a thin layer of cells sandwiched between the wood and inner bark, the two tissues it produces (**FIG. 35-5**).

As the stem increases in circumference, the number of cells in the vascular cambium also increases. This increase in cells occurs by an occasional radial division of a vascular cambium cell, at right angles to its normal direction of division. In this case, both daughter cells remain meristematic.

What happens to the original primary tissues of a stem once secondary growth develops? As a stem increases in thickness, the orientation of the original primary tissues changes. For example, secondary xylem and secondary phloem are laid down between the primary xylem and primary phloem within each vascular bundle. Therefore, as vascular cambium forms secondary tissues, the primary xylem and primary phloem in each vascular bundle become separated from each other. The primary tissues located outside the cylinder of secondary growth (i.e., primary phloem, cortex, and epidermis) are subjected to the mechanical pressures produced by secondary growth and are gradually crushed or torn apart and sloughed off.

Secondary tissues replace the primary tissues in function. Secondary xylem conducts water and dissolved minerals from roots to leaves in the woody plant. It contains the same types of cells found in primary xylem: water-conducting tracheids and vessel elements in addition to xylem parenchyma cells and fibers. The arrangement of the different cell types in secondary xylem produces the distinctive wood characteristics of each species.

Secondary phloem conducts dissolved sugar from its place of manufacture or of breakdown of starch to a place of use and storage. The same types of cells found in primary phloem (sieve tube elements, companion cells, phloem parenchyma cells, and fibers) are also found in secondary phloem, although secondary phloem usually has more fibers than primary phloem.

Secondary xylem and secondary phloem transport water, minerals, and sugar vertically throughout the woody plant body. However, materials must also move horizontally (laterally). Lateral movement occurs through *rays*, which are chains of parenchyma cells that radiate from the center of the woody stem or root (see **Fig. 35-5**). The vascular cambium forms rays, which are often continuous from the secondary xylem to the secondary phloem. Water and dissolved minerals are transported laterally through rays, from the secondary xylem to the secondary phloem. Likewise, rays form pathways for the lateral transport of dissolved sugar, from the secondary phloem to the secondary xylem,

The stems of many plants undergo secondary growth to increase in girth.

Figure 35-3 Development of secondary growth

Vascular cambium and the tissues it produces are shown in cross section; cork cambium is not depicted. (The figures change in scale because of space limitations; pith and primary xylem are actually the same size in all three diagrams, but the change in scale makes those tissues appear to shrink in each succeeding diagram.)

CONNECT How is the arrangement of the vascular bundles in a monocot stem unsuited to the functioning of a vascular cambium?

and of waste products to the center, or heart, of the tree (discussed later).

Cork cambium produces periderm Cork cambium, which usually arises from parenchyma cells in the outer

cortex, produces *periderm*, the functional replacement for the epidermis. Cork cambium is either a continuous cylinder of dividing cells (similar to vascular cambium) or a series of overlapping arcs of meristematic cells that form from parenchyma cells in successively deeper layers of the cortex and,

Figure 35-4 Divisions of a vascular cambium cell during a single growing season

To study the figure, start at the bottom and move up. Note that vascular cambium (*blue cell*) divides in two directions, forming secondary xylem (X) to the inside and secondary phloem (P) to the outside. These cells, which are numbered in the order in which they are produced, differentiate into the mature cell types associated with xylem and phloem. As secondary xylem accumulates, vascular cambium “moves” outward, and the woody stem increases in diameter.

eventually, secondary phloem. Variation in cork cambia and their rates of division explain why the outer bark of some tree species is fissured (as in bur oak), rough and shaggy (shag-bark hickory), scaly (Norway pine), or smooth and peeling (paper birch).

As is true of vascular cambium, cork cambium divides to form new tissues in two directions: to its inside and its outside. Cork cells, formed to the outside of cork cambium, are dead at maturity and have walls that contain layers of *suberin* and waxes, making them waterproof. These cork cells protect the woody stem against mechanical injury, mild fires, attacks by insects and fungi, temperature extremes, and water loss. To its inside, cork cambium sometimes forms cork parenchyma cells that store water and starch granules. Cork parenchyma is only one to several cells thick, much thinner than the cork cell layer.

Cork cells are impermeable to water and gases, yet the living internal cells of the woody stem require oxygen and

must be able to exchange gases with the surrounding atmosphere. As a stem thickens from secondary growth, the epidermis, including stomata that exchange gases for the herbaceous stem, dies. Stomata are replaced by **lenticels**, which permit gas exchange through the periderm (**FIG. 35-6**).

Woody twigs of deciduous trees bear characteristic features in winter A woody twig is that part of a branch produced during the current growing season. Twigs have **buds**, which are embryonic shoots. A **terminal bud** is the embryonic shoot located at the tip of a stem. The dormant (not actively growing) apical meristem of a terminal bud is covered and protected by an outer layer of **bud scales**, which are modified leaves (see Fig. 34-14c). **Axillary buds**, also called *lateral buds*, are located in the axils of a plant’s leaves (see Fig. 34-1). An *axil* is the upper angle between a leaf and the stem to which it is attached. When terminal and axillary buds grow, they form branches that bear leaves and/or flowers. The area on a stem where each leaf is attached is called a **node**, and the region between two successive nodes is an **internode**.

To demonstrate certain structural features of the stem, we can use a woody branch of a deciduous tree that has shed its leaves, as shown in **FIGURE 35-7**. Bud scales cover the terminal bud and protect its delicate apical meristem during dormancy. When the bud resumes growth, the bud scales covering the terminal bud

fall off, leaving **bud scale scars** on the stem where they were attached. Because temperate-zone woody plants form terminal buds at the end of each year’s growing season, the number of sets of bud scale scars on a twig indicates its age. A **leaf scar** shows where each leaf was attached on the stem; the pattern of leaf scars can be used to determine leaf arrangement on a stem: alternate, opposite, or whorled (see Fig. 34-2b). The vascular (conducting) tissue that extends from the stem out into the leaf forms **bundle scars** within a leaf scar. Axillary buds may be found above the leaf scars. Also, the bark of a woody twig has lenticels, which look like tiny specks on the bark of a twig.

Common terms associated with wood are based on plant structure If you have ever examined different types of lumber, you may have noticed that some trees have wood with two different colors (**FIG. 35-8**). The functional secondary xylem—the part that conducts water and dissolved

Figure 35-5 LM of a portion of a three-year-old basswood (*Tilia americana*) stem in cross section

minerals—is the *sapwood*, a thin layer of younger, lighter-colored wood that is closest to the bark. *Heartwood*, the older wood in the center of the tree, is typically a brownish red. A microscopic examination of heartwood reveals that its vessels and tracheids are plugged with pigments, tannins, gums, resins, and other materials. Therefore, heartwood no longer functions in conduction but instead functions as a storage site for waste products. Because it is denser than sapwood, heartwood provides structural support for trees. Some evidence suggests that heartwood is also more resistant to decay than sapwood.

Almost everyone has heard of hardwood and softwood. Botanically speaking, *hardwood* is the wood of flowering plants, and *softwood* is the wood of conifers (cone-bearing gymnosperms). The wood of pine and other conifers typically lacks fibers (with their thick secondary cell walls) and vessel elements; the conducting cells in gymnosperms are tracheids. These cell differences generally make conifer wood softer than the wood of

flowering plants, although there is a substantial variation from one species to another. The balsa tree, for example, is a flowering plant whose extremely light, soft wood is used to fashion airplane models.

Woody plants that grow in temperate climates where there is a growing period (during spring and summer) and a dormant period (during winter) exhibit *annual rings*, concentric circles found in cross sections of wood. To determine the age of a woody stem in the temperate zone, simply count the annual rings. In the tropics environmental conditions, particularly seasonal or year-round precipitation patterns, determine the presence or absence of rings, so rings are not a reliable method of determining the ages of most tropical trees.

Examination of annual rings with a magnifying lens reveals no actual “ring,” or line, separating one year’s growth from the next. The appearance of a ring in cross

Figure 35-6 LM of stem periderm, showing a lenticel

The epidermis has ruptured because of the proliferation of loosely arranged cork cells in the lenticel. From the bark of a calico flower (*Aristolochia elegans*) stem.

Figure 35-7 External structure of a woody branch in its winter condition

The age of a woody branch can be determined by the number of sets of bud scale scars (do not count side branches).

CONNECT How old is this branch? Can you point out any twigs?

year's growth and that formed at the beginning of the following year's growth. In the spring, when water is plentiful, wood formed by vascular cambium has large-diameter conducting cells (tracheids and vessel elements) and few fibers and is appropriately called *springwood* or *early wood* (see Fig. 35-5). As summer progresses and water becomes less plentiful, the wood formed, known as *summerwood* or *late wood*, has narrower conducting cells and many fibers. It is this difference in cell size between the summerwood of one year and the springwood of the following year that gives the appearance of rings.

Tree-ring analysis provides useful scientific information In temperate climates the number of annual rings indicates the age of a tree. The size of each ring varies depending on local weather conditions. Sometimes the variation can be attributed to a single environmental factor, and similar patterns appear in the rings of different species over a large geographic area. For example, years with adequate

Figure 35-8 Heartwood and sapwood

The wood of older trees consists of a dense central heartwood and an outer layer of sapwood. The sapwood is the functioning xylem that conducts water and dissolved minerals. The annual rings in the heartwood are very conspicuous.

precipitation produce wider growth rings, and years of drought produce narrower rings. It is possible to study ring sequences that are several thousand years old by constructing a *master chronology*, a complete sample of rings dating back as far as possible (Fig. 35-9).

Dendrochronology, the study of both visible and microscopic details of tree rings, has been used extensively in several fields. Tree-ring analysis has helped date Native American prehistoric sites in the Southwest. For example, using tree-ring analysis, scientists determined that the Cliff Palace in Mesa Verde National Park dates back to the year 1073. Tree-ring analysis is also useful in ecology (to study changes in a forest community over time), environmental science (to study the effects of air pollution on tree growth), and geology (to date earthquakes and volcanic eruptions).

Climatologists are increasingly using tree-ring data to study past climate patterns. Annual rings of certain tree species that grow at high elevations are sensitive to yearly temperature variations; the rings of these trees are wider in warm years and narrower in cool years. Studying tree rings over long periods helps researchers determine the natural pattern of global temperature fluctuations. This information is particularly important because of concerns about the human influence on global climate.

Although scientists generally agree that Earth has warmed in recent decades, they are not sure how much of the recent warming is the result of human influence rather than natural climate variability. To help answer this vital question, European scientists have been developing a 10,000-year master chronology that will help reconstruct annual temperatures across northern Europe and Asia since the end of the last Ice Age.

WHY IS IT USED? By matching the rings of a wood sample of unknown age to the master chronology, investigators can accurately determine the age of the sample. Tree-ring analysis provides useful information in a variety of fields, such as to date prehistoric sites, study past climate patterns, and date major prehistoric earthquakes.

HOW IS IT DONE? A master chronology is developed using progressively older pieces of wood from the same geographic area. A small core of wood is bored out of the trunk of a living tree. The oldest rings (toward the center of the tree) are matched with the youngest rings (toward the outside) of an older tree, perhaps a dead one in the forest. The master chronology is extended back in time by overlapping matching ring sequences of successively older and older sections of wood, even those found in prehistoric dwellings. Currently, the longest master chronology—of bristlecone pines in the western United States—goes back almost 9000 years. Ring matching, once a tedious, painstaking job, is performed by computers today.

Figure 35-9 How tree rings are analyzed

CHECKPOINT 35.1

- How does the arrangement of vascular tissue in cross section differ in primary eudicot stems and monocot stems?
- What is the difference between vascular cambium and cork cambium? What tissues arise from vascular cambium? from cork cambium?

- What happens to the primary tissues of a stem when secondary growth occurs?
- How do growth rings form in woody stems?
- What is the difference between terminal and axillary buds?

35.2 Water Transport

LEARNING OBJECTIVES

- 4 Describe the pathway of water movement in plants.
- 5 Define *water potential*.
- 6 Compare tension–cohesion and root pressure as mechanisms responsible for the rise of water and dissolved minerals in xylem.

Now that we have discussed stem structure and primary and secondary growth, we examine internal transport in the vascular system of the plant (FIG. 35-10). Roots obtain water and dissolved minerals from the soil. Once inside roots, these materials are transported upward to stems, leaves, flowers, fruits, and seeds. Furthermore, sugar molecules are transported from their place of manufacture or of breakdown of starch throughout the plant body, including into the subterranean roots. Water and dissolved minerals are transported from roots to other parts of the plant in xylem, whereas dissolved sugar is *translocated* in phloem.

Xylem transport and phloem translocation do not resemble the movement of materials in animals because in plants nothing *circulates* in a system of vessels. Water and minerals, transported in xylem, travel in one direction only (upward), whereas translocation of dissolved sugar may occur upward or downward in separate phloem cells. In addition, xylem transport and phloem translocation differ from internal circulation in animals because movement in both xylem and phloem is driven largely by natural physical processes rather than by a pumping organ, or heart.

How do materials travel in the continuous system of the plant’s vascular tissues? We first examine water and its movement through the plant, and later we discuss the translocation of dissolved sugar.

Water and minerals are transported in xylem

Water initially moves horizontally into roots from the soil, passing through several tissues until it reaches xylem. Once the water moves into the tracheids and vessel elements of root xylem, it travels upward through a continuous network of these hollow, dead cells from root to stem to leaf. Dissolved minerals are carried along passively in the water. The plant does not expend any energy of its own to transport water, which moves as a result of natural physical processes. The transport of xylem sap is the most rapid of any movement of materials in plants (TABLE 35-1).

Figure 35-10 Overview of transport in vascular plants

Xylem transport is explained on the *right side* of the figure (start at the bottom and work upward), and phloem transport is on the *left side*.

How does water move to the tops of plants? It is either pushed up from the bottom of the plant or pulled up by the top of the plant. Although plants use both mechanisms, current evidence indicates that most water is transported through xylem by being *pulled* to the top of the plant.

Table 35-1 Xylem and Phloem Transport Rates in Selected Plants

Plant	Maximum Rate in Xylem (cm/min)	Maximum Rate in Phloem (cm/min)
Conifer	2	0.8
Woody eudicot	73	2
Herbaceous eudicot or monocot	100	2.8–11
Herbaceous vine	250	1.2

Note: Xylem and phloem rates are from different plants within each general group and should be used for comparative purposes only.

Adapted from Mauseth, J.D., *Botany: An Introduction to Plant Biology*, 2nd ed. (Saunders College Publishing, Philadelphia, 1995).

Water movement can be explained by a difference in water potential

To understand how water moves, it is helpful to introduce **water potential**, which is defined as the **free energy** of water (see Chapter 7). Water potential (Ψ_w), represented by the Greek letter psi, is important in plant physiology because it is a measure of a cell's ability to absorb water by osmosis. (Recall from Chapter 5 and Figure 5-11 that **osmosis** is a special kind of diffusion that involves the net movement of water through a selectively permeable membrane from a region of higher effective concentration of water to a region of lower concentration.) Water potential also provides a measure of water's tendency to evaporate from cells.

The water potential of pure water is conventionally set at 0 megapascal (MPa) because it cannot be measured directly. (A megapascal is a unit of pressure equal to about 10.2 kg/cm², or 145.1 lb/in².) However, botanists can measure differences in the free energy of water molecules in different situations. When solutes dissolve in water, the free energy of water decreases. Solutes induce **hydration**, in which water molecules surround ions and polar molecules, keeping them in solution by preventing them from coming together (see Fig. 2-10). The association of water molecules with hydrated molecules and ions reduces the motion of water molecules, decreasing their free energy. Thus, dissolved solutes lower the water potential to a negative number. Water moves from a region of higher (less negative) water potential to a region of lower (more negative) water potential.

The water potential of the soil varies, depending on how much water it contains. When a soil is extremely dry, its water potential is very low (very negative). When a soil is moister, its water potential is higher, although it still has a negative value because dissolved minerals are present in dilute concentrations (TABLE 35-2).

The water potential in root cells is also negative because of the presence of dissolved solutes. Roots contain more dissolved materials than soil water does, unless the soil is extremely dry. This means that under normal conditions the water potential of the root is more negative than the water potential of the soil. Thus, water moves by osmosis from the soil into the root.

According to the tension-cohesion model, water is pulled up a stem

In 1896, Irish botanist Henry Dixon proposed the tension-cohesion model to explain the ascent of water against the

force of gravity. Although initially met with widespread skepticism in the scientific community, this model has withstood the test of time. According to the **tension-cohesion model**, also known as the **transpiration-cohesion model**, water is pulled up the plant as a result of a *tension* produced at the top of the plant (FIG. 35-11). This tension is caused by the evaporative pull of transpiration. Recall from Chapter 34 that **transpiration** is the evaporation of water vapor from plants.

Most water loss from transpiration takes place through stomata, the numerous microscopic pores present on leaf and stem surfaces. Water vapor diffuses through the stomata into a boundary layer of quiet air adjacent to the leaf surface. The *boundary layer* is thicker when the wind is calm than when it is gusty; a thicker boundary layer results in a slower rate of transpiration.

The tension extends from leaves, where most transpiration occurs, down the stems and into the roots. It draws water up stem xylem to leaf cells that have lost water as a result of transpiration and pulls water from root xylem into stem xylem. As water is pulled upward, additional water from the soil is drawn into the roots. Thus, the pathway of water movement is as follows:

soil → root tissues (epidermis, cortex, etc.) → root xylem → stem xylem → leaf xylem → leaf mesophyll → atmosphere

This upward pulling of water is possible only as long as there is an unbroken column of water in xylem throughout the plant. Water forms an unbroken column in xylem because water molecules exhibit **cohesion**—that is, they are strongly attracted to one another—due to **hydrogen bonding**. In addition, the **adhesion** of water to the walls of xylem cells, also the result of hydrogen bonding, is an important factor in maintaining an unbroken column of water. Thus, the cohesive and adhesive properties of water enable it to form a continuous column that can be pulled up through the xylem.

The movement of water in xylem by the tension-cohesion mechanism can be explained in terms of water potential. The atmosphere has an extremely negative water potential. For example, air with a relative humidity of 50% has a water potential of -100 MPa; even moist air at a relative humidity of 90% has a negative water potential of -13 MPa. Thus, there is a water potential gradient from the least negative (the soil) up through the plant to the most negative (the atmosphere). This gradient literally pulls the water from the soil up through the plant.

Although the tension-cohesion model was first proposed toward the end of the 19th century, conclusive experimental evidence to support this mechanism was not obtained until the late 1990s and early 2000s. At that time, several research groups made direct measurements of the large negative pressure that exists in xylem, indicating that the water potential gradients in root, stem, and leaf xylem are adequate to explain the observed movement of water.

Is the tension-cohesion model powerful enough to explain the rise of water in the tallest plants? Plant biologists have studied this question for years. For example, a 2004 study of five of the eight tallest trees in the world (all redwoods, or *Sequoia sempervirens*) concluded that the tension produced

Table 35-2 Representative Water Potential (Ψ_w) Values

Plant Parts and the Nearby Environment	Water Potentials in Megapascals (MPa)
Atmosphere near leaves	-80.0
Leaf interior	-1.5
Stem xylem	-0.7
Root interior	-0.4
Soil water	-0.1

Note: Actual values vary widely, depending on environmental factors such as solute concentration, hydrostatic pressure, and gravity.

Transpiration is the driving force of the tension–cohesion model.

Figure 35-11 The tension–cohesion model

PREDICT What do you think would happen if solutes added to the soil water were to make its water potential more negative than that of the root tissue?

by transpiration is strong enough to pull water upward to a maximum height of 130 m (422 ft). Because the height of the tallest known living tree, a coast redwood in California, measured 115.7 m (379 ft) in 2007, the tension–cohesion model easily accounts for the transport of water. Botanists generally consider the tension–cohesion model to be the dominant mechanism of xylem transport in most plants.

Root pressure pushes water from the root up a stem

In the less important mechanism for water transport, known as **root pressure**, water that moves into roots from the soil is *pushed* up through xylem toward the top of the plant. Root pressure occurs because mineral ions that are actively

absorbed from the soil are pumped into the xylem, decreasing its water potential. This accumulation of ions has an osmotic effect, causing water to move into xylem cells from surrounding root cells. In turn, water moves into roots by osmosis because of the difference in water potential between the soil and root cells. The accumulation of water in root tissues produces a positive pressure (as high as +0.2 MPa) that forces the water up through the root xylem into the shoot.

Guttation, a phenomenon in which liquid water is forced out through special openings in the leaves (see Fig. 34-12), results from root pressure. However, root pressure is not strong enough to explain the rise of water to the tops of tall trees. Root pressure exerts an influence in much smaller plants, particularly in the spring when the soil is moist, but it clearly does not cause water to rise to the tops of the tallest plants. Furthermore, root pressure does not occur to any appreciable extent in summer (when water is often not plentiful in soil), yet water transport is greatest during hot summer days.

CHECKPOINT 35.2

- **CONNECT** How is the movement of water in a plant related to water potential?
- How does the tension–cohesion model explain the rise of water in the tallest trees?

35.3 Translocation of Sugar in Solution

LEARNING OBJECTIVES

- 7 Describe the pathway of sugar translocation in plants.
- 8 Discuss the pressure–flow model of sugar translocation in phloem.

The sugar produced during photosynthesis is converted into sucrose (common table sugar), a disaccharide composed of one molecule of glucose and one of fructose (see Fig. 3-8b), before being loaded into phloem and translocated to the rest of the plant. Sucrose is the predominant photosynthetic product carried in phloem. Phloem sap also contains much smaller amounts of other materials, such as amino acids, organic acids, proteins, hormones, and certain minerals (e.g., potassium, chloride, phosphate, and magnesium). Sometimes disease-causing plant viruses are transported throughout the plant in phloem. Translocation of phloem sap is not as rapid as xylem transport (see Table 35-1).

Fluid within phloem tissue moves both upward and downward. Sucrose is translocated in individual sieve tubes from a *source*, an area of excess sugar supply (usually a leaf), to a *sink*, an area of storage (as insoluble starch) or of sugar use, such as roots, apical meristems, fruits, and seeds.

The pressure–flow model explains translocation in phloem

Current experimental evidence supports the **translocation** of dissolved sugar in phloem by the **pressure–flow model**, which was first proposed in 1926 by German scientist Ernst Münch. The pressure–flow model states that solutes (such as dissolved sugars) move in phloem by means of a pressure gradient, that is, a difference in pressure. The pressure gradient exists between the source, where the sugar is loaded into phloem, and the sink, where the sugar is removed from phloem.

At the source, the dissolved sucrose is moved from a leaf's mesophyll cells, where it was manufactured, into the companion cells, which load sucrose into the sieve tube elements of phloem. Sucrose loading occurs by active transport, a process that requires adenosine triphosphate (ATP) (FIG. 35-12). The ATP supplies energy to pump protons (H^+) out of the sieve tube elements, producing a proton gradient that drives the uptake of sugar through specific channels by the **cotransport** of protons back into the sieve tube elements. (Recall the discussion of a cotransport system in Chapter 5.) In the cotransport system involved in phloem loading, sugar is moved from a region of low concentration to a region of high concentration by coupling its transport to the transport of protons down their concentration gradient.

The sugar therefore accumulates in the sieve tube element. The increase in dissolved sugars in the sieve tube element at the source—a concentration that is two to three times as great as in surrounding cells—decreases (makes more negative) the water potential of that cell. As a result, water moves by osmosis from nearby xylem cells into the sieve tubes, increasing the **turgor pressure** (hydrostatic pressure) inside them. Thus, phloem loading at the source occurs as follows:

proton pump moves H^+ out of sieve tube element → sugar is actively transported into sieve tube element → water diffuses from xylem into sieve tube element → turgor pressure increases within sieve tube

At its destination (the sink), sugar is unloaded by various mechanisms, both active and passive, from the sieve tube elements. With the loss of sugar, the water potential in the sieve tube elements at the sink increases (becomes less negative). Therefore, water moves out of the sieve tubes by osmosis and into surrounding cells where the water potential is more negative. Most of this water diffuses back to the xylem to be transported upward. This water movement decreases the turgor pressure inside the sieve tubes at the sink. Thus, phloem unloading at the sink proceeds as follows:

sugar is transported out of sieve tube element → water diffuses out of sieve tube element and into xylem → turgor pressure decreases within sieve tube

Key Point

In phloem, solutes move from sources to sinks. The pressure gradient within the sieve tube causes translocation from the area of higher turgor pressure (the source) to the area of lower turgor pressure (the sink).

Figure 35-12 The pressure-flow model

PREDICT In what direction would transport occur in the phloem if the source were starch being broken down in a storage root in the spring and the sink were a developing leaf?

The pressure-flow model explains the movement of dissolved sugar in phloem by means of a pressure gradient. The difference in sugar concentrations between the source

and the sink causes translocation in phloem as water and dissolved sugar flow along the pressure gradient. This pressure gradient pushes the sugar solution through phloem much as water is forced through a hose.

The actual translocation of dissolved sugar in phloem does not require metabolic energy. However, the loading of sugar at the source and the active unloading of sugar at the sink require energy derived from ATP to move the sugar across cell membranes by active transport.

Although the pressure-flow model adequately explains current data on phloem translocation, much remains to be learned about this complex process. Phloem translocation is difficult to study in plants. Because phloem cells are under pressure, cutting into phloem to observe it releases the pressure and causes the contents of the sieve tube elements (the phloem sap) to exude and mix with the contents of other severed cells that are also unavoidably cut. In the 1950s, scientists developed a unique research tool to avoid contaminating the phloem sap: aphids, which are small insects that insert their mouthparts into phloem sieve tubes for feeding (**FIG. 35-13**). The pressure in the punctured phloem drives the sugar solution through the aphid's mouthpart into its digestive system. When the aphid's mouthpart is severed from its body by a laser beam, the sugar solution continues to flow through the mouthpart at a rate proportional to the pressure in phloem. This rate can be measured, and the effects on phloem transport of different environmental conditions—varying light intensities, darkness, and mineral deficiencies, for example—can be ascertained.

The identity and proportions of translocated substances can also be determined using severed aphid mouthparts. This technique has verified that in most plant species the sugar sucrose is the primary carbohydrate transported in phloem; however, some species transport other sugars, such as raffinose, or sugar alcohols, such as sorbitol.

CHECKPOINT 35.3

- How does the direction of transport differ in xylem and phloem?
- How does the pressure-flow model explain sugar movement in phloem? Include in your answer the activities at source and sink.

Key Experiment

How can phloem sap be studied without cutting non-phloem cells that would contaminate the sap?

HYPOTHESIS: An aphid mouthpart can be used to penetrate a single sieve tube.

EXPERIMENT: After allowing aphids to insert their mouthparts into phloem of a stem, researchers anesthetized the feeding aphids with CO₂ and used a laser to cut their bodies away from their mouthparts. The mouthparts remained in the phloem and functioned like miniature pipes.

Figure 35-13 Collecting and analyzing phloem sap

This method, first used in the 1950s by insect physiologists studying aphids, was quickly adopted by plant physiologists studying phloem translocation.

PREDICT Would you expect to observe outward movement of fluid through the aphid's mouthpart if the stem xylem of a large plant were penetrated?

Summary: Focus on Learning Objectives

35.1 Stem Growth and Structure (page 746)

1 Sketch cross sections of herbaceous eudicot and monocot stems, and describe the functions of each tissue.

- Herbaceous stems possess an epidermis, vascular tissue, and either ground tissue or cortex and pith. The **epidermis** is a protective layer covered by a water-conserving **cuticle**. **Stomata** permit gas exchange. **Xylem** conducts water and dissolved minerals, and **phloem** conducts dissolved sugar. The **cortex**, **pith**, and ground tissue function primarily for storage.
- All herbaceous stems have the same basic tissues, but their arrangement varies. Herbaceous eudicot stems have the vascular bundles arranged in a circle (in cross section) and have a distinct cortex and pith. Monocot stems have vascular bundles scattered in ground tissue.

2 Name the two lateral meristems and describe the tissues that arise from each.

- Vascular cambium** is the lateral meristem that produces secondary xylem (wood) and secondary phloem (inner bark).
- Cork cambium** produces **periderm**, which consists of cork parenchyma and cork cells. Cork cells are the functional replacement for epidermis in a woody stem. Cork parenchyma functions primarily for storage in a woody stem.

3 Outline the transition from primary growth to secondary growth in a woody stem.

- Secondary growth** (the production of the secondary tissues, wood and bark) occurs in some flowering plants (woody eudicots) and in all cone-bearing gymnosperms. During secondary growth, the vascular cambium divides in two directions to form secondary xylem (to the inside) and secondary phloem (to the outside). The primary xylem and primary phloem in the original vascular bundles become separated as secondary growth proceeds.

35.2 Water Transport (page 754)

4 Describe the pathway of water movement in plants.

- Water and dissolved minerals move from the soil into root tissues (epidermis, cortex, etc.). Once in root xylem, water and minerals move upward, from root xylem to stem xylem to leaf xylem. Much of the water entering the leaf exits leaf veins and passes into the atmosphere.

5 Define water potential.

- Water potential (Ψ_w)** is a measure of the **free energy** of water. Pure water has a water potential of 0 megapascal (MPa), whereas water with dissolved solutes has a negative

water potential. Water moves from an area of higher (less negative) water potential to an area of lower (more negative) water potential.

6 Compare tension–cohesion and root pressure as mechanisms responsible for the rise of water and dissolved minerals in xylem.

- The **tension–cohesion model** explains the rise of water in even the tallest plants. The evaporative pull of **transpiration** causes tension at the top of the plant. This tension is the result of a water potential gradient that ranges from the slightly negative water potentials in the soil and roots to the very negative water potentials in the atmosphere. As a result of the **cohesion** of water molecules to each other and their **adhesion** to the xylem cell walls, the column of water pulled up through the plant remains unbroken.
- Root pressure**, caused by the movement of water into roots from the soil as a result of the active absorption of mineral ions from the soil, helps explain the rise of water in smaller plants, particularly when the soil is wet. Root pressure pushes water up through xylem.

35.3 Translocation of Sugar in Solution (page 757)

7 Describe the pathway of sugar translocation in plants.

- Translocation** of dissolved sugar occurs upward or downward in phloem, from a source (an area of excess sugar, usually a leaf) to a sink (an area of storage or of sugar use, such as roots, apical meristems, fruits, and seeds). Sucrose is the predominant sugar translocated in phloem.

8 Discuss the pressure–flow model of sugar translocation in phloem.

- Movement of materials in phloem is explained by the **pressure–flow model**. Companion cells actively load sugar into the sieve tubes at the source; ATP is required for this process. The ATP supplies energy to pump protons out of the sieve tube elements. The proton gradient drives the uptake of sugar by the cotransport of protons back into the sieve tube elements. Sugar therefore accumulates in the sieve tube element, causing the movement of water into the sieve tubes by **osmosis**.
- Companion cells actively (requiring ATP) and passively (not requiring ATP) unload sugar from the sieve tubes at the sink. As a result, water leaves the sieve tubes by osmosis, decreasing the **turgor pressure** (hydrostatic pressure) inside the sieve tubes.
- The flow of materials between source and sink is driven by the turgor pressure gradient produced by water entering phloem at the source and water leaving phloem at the sink.

Test Your Understanding

Know and Comprehend

1. Axillary buds are located (a) at the tips of stems (b) in unusual places, such as on roots (c) in the region between two successive nodes (d) in the upper angle between a leaf and the stem to which it is attached (e) within the loosely arranged cells of lenticels
2. Ground tissue in monocot stems performs the same functions as _____ and _____ in herbaceous eudicot stems. (a) phloem; xylem (b) cork cambium; vascular cambium (c) epidermis; periderm (d) primary xylem; secondary xylem (e) cortex; pith
3. Which of the following statements is *false*? (a) primary growth is an increase in the length of a plant (b) primary growth occurs at both apical and lateral meristems (c) all plants have primary growth (d) herbaceous stems have primary growth, whereas woody stems have both primary and secondary growth (e) buds are embryonic shoots that contain apical meristems
4. The two lateral meristems responsible for secondary growth are (a) phloem and xylem (b) cork cambium and vascular cambium (c) epidermis and periderm (d) primary xylem and secondary xylem (e) cortex and pith
5. Cork cambium and the tissues it produces are collectively called (a) periderm (b) lenticels (c) cortex (d) epidermis (e) wood
6. Each annual ring in a section of wood represents one year's growth of (a) primary xylem (b) secondary xylem (c) primary xylem or secondary xylem in alternate years (d) primary phloem (e) secondary phloem
7. Water potential is (a) the formation of a proton gradient across a cell membrane (b) the transport of a watery solution of sugar in phloem (c) the transport of water in both xylem and phloem (d) the removal of sucrose at the sink, causing water to move out of the sieve tubes (e) the free energy of water in a particular situation
8. Which of the following is a mechanism of water movement in xylem that is responsible for guttation? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) transpiration
9. Which of the following is a mechanism of water movement in xylem that combines the evaporative pull of transpiration with the cohesive and adhesive properties of water? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation

10. Which of the following is a mechanism of phloem transport in which dissolved sugar is moved by means of a pressure gradient that exists between the source and the sink? (a) pressure–flow (b) tension–cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation
11. How does increasing solute concentration affect water potential? (a) water potential becomes more positive (b) water potential becomes more negative (c) water potential becomes more positive under certain conditions and more negative under other conditions (d) water potential is not affected by solute concentration (e) water potential is always zero when solutes are dissolved in water

Apply and Analyze

12. **VISUALIZE** Sketch side by side two daughter cells formed after mitosis of a meristematic cell in the vascular cambium of a eudicot stem. Label the cell formed toward the interior of the stem a meristematic cell. Should the daughter cell formed toward the outside be labeled primary xylem, primary phloem, secondary xylem, or secondary phloem?

Evaluate and Synthesize

13. When a strip of bark is peeled off a tree branch, what tissues are usually removed?
14. Could a tree grow to a height of 150 m (488 ft)? Why or why not?
15. **EVOLUTION LINK** Like stems in general, some vines are herbaceous and others are woody. Tropical rain forests have a greater diversity of vines than in any other environment on Earth, and most of these vines are woody. Develop a hypothesis to explain why natural selection has favored the evolution of more species of woody vines (as opposed to herbaceous vines) in tropical rain forests.
16. **INTERPRET DATA** A plant cell with a water potential $\Psi_w = -1.5$ MPa is adjacent to a second cell with $\Psi_w = -1.8$ MPa. Will water flow by osmosis from one cell to the other? If so, in which direction?

36 Roots and Mineral Nutrition

KEY CONCEPTS

- 36.1** Root structure is related to function. Primary tissues (epidermis, cortex, endodermis, pericycle, xylem, and phloem) of roots develop from root apical meristems. Secondary tissues (wood and bark) of woody roots develop from lateral meristems.
- 36.2** Roots associate and interact with many organisms, including soil bacteria and fungi.
- 36.3** Soil, the layer of Earth's crust that has been modified by contact with weather, wind, water, and organisms, contains most of the essential elements required by plants.

PHOTO: Storage roots. Cassava (*Manihot esculenta*) plants have been dug up to show the growth habit of the storage roots. Cassava roots are an important staple crop in the tropics. Some cassava roots contain a poison (prussic acid), which is destroyed during cooking. Inga Spence/Alamy Stock Photo

Branching underground root systems are often more extensive than a plant's aerial parts. The roots of a corn plant, for example, may grow to a depth of 2.5 m (about 8 ft) and spread outward 1.2 m (4 ft) from the stem. Desert-dwelling tamarisk (*Tamarix*) trees reportedly have roots that grow to a depth of 50 m (163 ft) to tap underground water. The extent of a plant's root depth and spread varies considerably among different species and even among different individuals in the same species.

Because roots are usually underground and out of sight, people do not always appreciate the important functions they perform. First, as anyone who has ever pulled weeds can attest, roots anchor a plant securely in the soil. A plant needs a solid foundation from which to grow. Firm anchorage is essential to a plant's survival so that the stem remains upright, enabling leaves to absorb sunlight effectively. Second, roots absorb water and dissolved minerals (inorganic nutrients) such as nitrates, phosphates, and sulfates, which are necessary for synthesizing important organic molecules. These dissolved minerals are then transported throughout the plant in the xylem.

Many roots perform the function of storage. Carrots, sweet potatoes, cassava, and other root crops are important sources of human food (see photograph). Surplus sugars produced in the leaves by photosynthesis are transported in the phloem to the roots for food storage (usually as starch or sucrose) until needed. Other plants, particularly those living in arid regions, possess storage roots adapted to store water.

In certain species roots are modified for functions other than anchorage, absorption, conduction, and storage. Roots specialized to perform uncommon functions are discussed later in the chapter.

36.1 Root Structure and Function

LEARNING OBJECTIVES

- 1 Distinguish between taproot and fibrous root systems.
- 2 Compare cross sections of a primary eudicot root and a monocot root, and describe the functions of each tissue.
- 3 Trace the pathway of water and mineral ions from the soil through the various root tissues and distinguish between the symplast and apoplast.
- 4 Discuss the structure of roots with secondary growth.
- 5 Describe at least three roots that are modified to perform uncommon functions.

Two types of root systems, a taproot system and a fibrous root system, occur in plants (**FIG. 36-1**). A **taproot system** consists of one main root that formed from the seedling's enlarging **radicle**, or embryonic root. Many lateral roots of various sizes branch out of a taproot. Taproots are characteristic of many eudicots and gymnosperms. A dandelion is a good example of a common herbaceous plant with a taproot system. A few trees, such as hickory, retain their taproots, which become quite massive as the plants age. Most trees, however, have taproots when young and later develop large, shallow, lateral roots from which other roots branch off and grow downward.

(a) A taproot system develops from the embryonic root in the seed.

(b) The roots of a fibrous root system are adventitious and develop from stem tissue.

Figure 36-1 Root systems

A **fibrous root system** has several to many roots of similar size developing from the end of the stem, with lateral roots branching off these roots. Fibrous root systems form in plants that have a short-lived embryonic root. The roots originate first from the base of the embryonic root and later from stem tissue. The main roots of a fibrous root system do not arise from pre-existing roots but from the stem; such roots are called **adventitious** roots. Adventitious organs occur in an unusual location, such as roots that develop on a stem or buds that develop on roots. Onions, crabgrass, and other monocots have fibrous root systems.

Taproot and fibrous root systems are adapted to obtain water in different sections of the soil. Taproot systems often extend down into the soil to obtain water located deep underground, whereas fibrous root systems, which are located relatively close to the soil surface, are adapted to obtain rainwater from a larger area as it drains into the soil.

Roots have root caps and root hairs

Because of the need to adapt to the soil environment instead of the atmospheric environment, roots have several structures, such as root caps and root hairs, that shoots lack. Although stems and leaves have various types of hairs, they are distinct from root hairs in structure and function.

Each root tip is covered by a **root cap**, a protective, thimblelike layer many cells thick that covers the delicate root **apical meristem** (**FIG. 36-2a**; also see Fig. 33-6). As the root grows, pushing its way through the soil, cells of the root cap are sloughed off by the frictional resistance of the soil particles and replaced by new cells formed by the root apical meristem. The root cap cells secrete lubricating polysaccharides that reduce friction as the root passes through the soil. The root cap also appears to be involved in orienting the root so that it grows downward (see discussion of gravitropism in Chapter 38). When a root cap is removed, the root apical meristem grows a new cap. However, until the root cap has regenerated, the root grows randomly rather than in the direction of gravity.

Root hairs are short-lived tubular extensions of epidermal cells located just behind the growing root tip. Root hairs continually form in the area of cell maturation closest to the root tip to replace those that are dying off at the more mature end of the root-hair zone (**FIG. 36-2b**; also see Fig. 33-6). Each root hair is short (typically less than 1 cm, or 0.4 in., in length), but they are quite numerous. Root hairs greatly increase the absorptive capacity of roots by increasing their surface area in contact with moist soil. Soil particles are coated with a microscopically thin layer of water in which minerals are dissolved. The root hairs establish an intimate contact with soil particles, which allows efficient absorption of water and minerals. They also modify the composition of the soil by exuding a diverse array of organic molecules.

Scientists are actively studying the control of root hair development. Through investigations using the model angiosperm *Arabidopsis thaliana*, it has been learned that the spatial arrangement of root hairs in the root epidermis is a consequence of complex interactions between cells that form root hairs and adjacent cells that do not. Many of the genes involved

to have its genome sequenced (see Fig. 27-11). Mosses such as *Physcomitrella* represent an ancient lineage of land plants thought to have diverged from the line leading to vascular plants about 420 million years ago. It therefore appears that these genes were conserved during the evolution from a dominant gametophyte in mosses to a dominant sporophyte in flowering plants.

The arrangement of vascular tissues distinguishes the roots of herbaceous eudicots and monocots

Although considerable variation exists in herbaceous eudicot and monocot roots, they all have an outer protective covering (epidermis), a cortex for storage of starch and other organic molecules, and vascular tissues for conduction. Let us first consider the structure of herbaceous eudicot roots.

In most herbaceous eudicot roots, the central core of vascular tissue lacks pith The buttercup root is a representative eudicot root with primary growth (FIG. 36-3). Like other parts of this herbaceous eudicot, a single layer of

code for **transcription factors**. (You may recall from Chapter 14 that transcription factors are DNA-binding proteins that regulate the synthesis of RNA from a DNA template.) Some of these genes have been shown to have an ancient origin with evolutionary significance. Researchers have demonstrated that two genes that code for transcription factors involved in the control of root hair formation in the sporophyte stage of *Arabidopsis* are essentially the same as two genes that control rhizoid formation in the gametophyte stage of *Physcomitrella patens*, the first moss

(b) Stele of eudicot root. Surrounding the solid core of vascular tissues is a single layer of pericycle, which is meristematic in growing roots.

Figure 36-3 LMs of cross sections of a herbaceous eudicot root. Shown is a buttercup (*Ranunculus*) root.

The **symplast pathway (blue)** consists of living cells interconnected by **plasmodesmata**. The **apoplast pathway (red)** uses cell walls and intercellular spaces.

Figure 36-4 Pathways of water and dissolved minerals in the root

Water and dissolved minerals travel from cell to cell along the interconnected porous cell walls (the apoplast) or from one cell's cytoplasm to another through plasmodesmata (the symplast). On reaching the endodermis, water and minerals can move into the root's center only if they pass through a plasma membrane and enter the cytoplasm of an endodermal cell.

PREDICT Would you expect to find minerals not needed by the plant in the apoplast? in the symplast? Explain your answer.

protective tissue, the **epidermis**, covers its roots. The root hairs are a modification of the root epidermis that enables it to absorb more water from the soil. The root epidermis does not secrete a thick, waxy cuticle in the region of root hairs because this layer would impede the absorption of water from the soil. Both the lack of a cuticle and the presence of root hairs increase absorption.

Beginning with the root hairs, most of the water that enters the root moves along the cell walls rather than enters the cells. A major component of cell walls is cellulose, which absorbs water as a sponge does. An example of the absorptive properties of cellulose is found in cotton balls, which are almost pure cellulose.

The root **cortex**, which is made up primarily of loosely packed **parenchyma** cells, composes the bulk of a herbaceous eudicot root. Roots usually lack supporting **collenchyma** cells, probably because the soil supports the root, although roots as they age may develop some **sclerenchyma** (another supporting tissue; see Chapter 33). The primary function of the root cortex is storage. A microscopic examination of the parenchyma cells that form the cortex often reveals numerous amyloplasts (see Figs. 36-3b and 3-9a), which store starch. Starch, an

insoluble carbohydrate composed of glucose subunits, is the most common form of stored energy in plants. When used at a later time, these reserves provide energy for such activities as growth and cell replacement following an injury.

The large intercellular (between-cell) spaces, a common feature of the root cortex, provide a pathway for water uptake and allow for aeration of the root. The oxygen that root cells need for aerobic respiration diffuses from air spaces in the soil into the intercellular spaces of the cortex and from there into the cells of the root.

The water and dissolved minerals that enter the root cortex from the epidermis move in solution along two pathways: the symplast and the apoplast (FIG. 36-4). The **symplast** is the continuum of living cytoplasm, which is connected from one cell to the next by cytoplasmic bridges called **plasmodesmata** (see Fig. 5-24). Some dissolved mineral ions move from the epidermis through the cortex via the symplast. The **apoplast** consists of the interconnected porous cell walls of a plant along which water and mineral ions move freely. The water and mineral ions can diffuse across the cortex without ever crossing a plasma membrane to enter a living cell. Together the symplast and apoplast make up the entire plant body.

The endodermis regulates the kinds of minerals that are absorbed from the soil and conducted to the rest of the plant body.

Figure 36-5 Endodermis and mineral uptake

Note the Casparian strip around the radial and transverse walls that prevents water and dissolved minerals from passing into the stele along endodermal cell walls. To reach the vascular tissues, water and dissolved minerals must pass through the plasma membranes of endodermal cells.

CONNECT Does the entry of water from the apoplast into the endodermal cells require a direct or indirect input of metabolic energy? Explain your answer.

The inner layer of the cortex, the **endodermis**, regulates the movement of water and minerals that enter the xylem in the root's center. Structurally, the endodermis differs from the rest of the cortex. Endodermal cells fit snugly against one another, and each has a special bandlike region, called a **Casparian strip** (FIG. 36-5), on its radial (side) and transverse (upper and lower) walls. Casparian strips contain *suberin*, a fatty material that is waterproof. (Recall from Chapter 33 that suberin is also the waterproof material in cork cell walls.)

Until the endodermis is reached, most of the water and dissolved minerals have traveled along the apoplast and therefore have not passed through a plasma membrane or entered the cytoplasm of a root cell. However, the waterproof Casparian strip on the radial and transverse walls of the endodermal cells prevents water and minerals from continuing to move passively along the cell walls. For substances to pass farther into the root interior, they must move from the cell walls into the cytoplasm of the endodermal cells. Water enters by osmosis, both directly across the lipid bilayer of the endodermal plasma membrane and through **aquaporins**, integral membrane proteins that facilitate the rapid transport of water across the membrane (FIG. 36-6a). As in water movement across the lipid bilayer, water moves through aquaporins only along the osmotic gradient, from a region of higher effective water concentration to a region of lower water concentration. The key role of aquaporins in the uptake of water by root cells is currently under active study.

Minerals enter endodermal cells by passing through carrier proteins in their plasma membranes. In **carrier-mediated active transport**, the mineral ions are pumped *against* their concentration gradient—that is, from an area of *low* concentration of

that mineral in the soil solution to an area of *high* concentration in the plant's cells (FIG. 36-6b). One of many reasons root cells require sugar and oxygen for aerobic respiration is that this active transport requires the expenditure of energy, usually in the form of ATP. From the endodermis, water and mineral ions enter the root xylem (botanists do not yet know precisely how this is done) and are conducted to the rest of the plant.

At the center of a eudicot primary root is the **stele**, or **vascular cylinder**, a central cylinder of vascular tissues. The outermost layer of the stele is the **pericycle**, which is just inside the endodermis. The pericycle consists of a single layer of parenchyma cells that give rise to multicellular *lateral roots*, also called branch roots (FIG. 36-7). Lateral roots originate when cells in a portion of the pericycle start dividing. As it grows, the lateral root pushes through several layers of root tissue (endodermis, cortex, and epidermis) before entering the soil. Each lateral root has all the structures and features—root cap, root hairs, epidermis, cortex, endodermis, pericycle, xylem, and phloem—of the larger root from which it emerges. In addition to producing lateral roots, the pericycle is involved in forming the lateral meristems that produce secondary growth in woody roots (discussed later in the chapter).

Xylem, the centermost tissue of the stele, often has two, three, four, or more extensions, or “xylem arms” (see Fig. 36-3b). **Phloem** is located in patches between the xylem arms. The xylem and phloem of the root have the same functions and kinds of cells as in the rest of the plant: water and dissolved minerals are conducted in **tracheids** and **vessel elements** of xylem, and dissolved sugar (sucrose) is conducted in **sieve tube elements** of phloem.

(a) Movement of water. Water crosses membranes by diffusion through the lipid layer (left) and, more rapidly, through aquaporins (right).

(b) Movement of mineral ions by carrier-mediated active transport. The lipid bilayer of plant membranes is impermeable to mineral ions, which can only pass through ion transport channels. The hydrolysis of ATP pumps protons outside the cell, forming an energy-charged proton gradient. Ion transport channels allow mineral ions to enter the cell with protons.

Figure 36-6 Transport of water and minerals across plant membranes

After passing through the endodermal cells, water enters the root xylem, often at one of the xylem arms. Up to this point, the pathway of water has been horizontal from the soil into the center of the root:

root hair/epidermis → cortex → endodermis → pericycle → root xylem

Once water enters the xylem, it is transported upward through root xylem into stem xylem and from there to the rest of the plant.

One direction of phloem conduction is from the leaves, where sugar is made by photosynthesis, to the root, where sugar is used for the growth and maintenance of root tissues or stored,

Figure 36-7 LM of a lateral root
Lateral roots originate at the pericycle.

usually as starch. Another direction of phloem conduction is from the root, where sugar is stored as starch, to other parts of the plant, where sugar is used for growth and maintenance of tissues.

The *vascular cambium*, which gives rise to secondary tissues in woody plants, is sandwiched between the xylem and phloem. Because it has an inner core of vascular tissue, the primary eudicot root lacks **pith**, a ground tissue found in the centers of many stems and roots.

Xylem does not form the central tissue in some monocot roots Monocot roots vary considerably in internal structure compared with eudicot roots. The layers found in some monocot roots, starting from the outside, are epidermis, cortex, endodermis, and pericycle (**FIG. 36-8**). Unlike the xylem in herbaceous eudicot roots, the xylem in many monocot roots does not form a solid cylinder in the center. Instead, the phloem and xylem are in separate, alternating bundles arranged around the central pith, which consists of parenchyma cells.

Because virtually no monocots have secondary growth, no vascular cambium exists in monocot roots. Despite their lack of secondary growth, long-lived monocots, such as palms, may have thickened roots produced by a modified form of primary growth in which parenchyma cells in the cortex divide and enlarge.

Woody plants have roots with secondary growth

Plants that produce stems with secondary growth also produce roots with secondary growth. These plants—gymnosperms and woody eudicots—have primary growth at

Figure 36-8 LM of a cross section of a monocot root
Shown is a greenbrier (*Smilax*) root. As in herbaceous eudicot roots, the cortex of a monocot root is extensive.

apical meristems and secondary growth at lateral meristems. The production of secondary tissues occurs some distance back from the root tips and results from the activity of the same two lateral meristems found in woody stems: the vascular cambium and the cork cambium. Major roots of trees are often massive and have both wood and bark. In temperate climates the wood of both roots and stems exhibits annual rings in cross section.

Before secondary growth starts in a root, the **vascular cambium** is sandwiched between the primary xylem and the primary phloem (FIG. 36-9). At the onset of secondary growth, the vascular cambium extends out to the pericycle, which develops into vascular cambium opposite the xylem arms. As a result, the pericycle links the separate sections of vascular cambium so that the vascular cambium becomes a continuous, noncircular loop of cells in cross section. As the vascular cambium divides to produce secondary tissues, it eventually forms a cylinder of vascular cambium that continues to divide, producing secondary xylem (wood) to the inside and secondary phloem (inner bark) to the outside. The root increases in girth (thickness), and the vascular cambium continues to move outward.

The epidermis, cortex, endodermis, and primary phloem are gradually torn apart as the root increases in girth. The root epidermis is replaced by **periderm**, composed of cork cells and cork parenchyma, both produced by the **cork cambium** (the last figure in Table 33-4 shows an LM of periderm). The cork cambium in the root initially arises from regions in the pericycle.

Some roots are specialized for unusual functions

Adventitious roots often arise from the nodes of stems. Many aerial adventitious roots are adapted for functions other than anchorage, absorption, conduction, or storage. **Prop roots** are adventitious roots that develop from branches or a vertical stem and grow downward into the soil to help support the plant in an upright position (FIG. 36-10a). Prop roots are more common in monocots than in eudicots. Corn and sorghum, both monocots, are herbaceous plants that produce prop roots. Many tropical and subtropical eudicot trees, such as red mangrove, also produce prop roots.

The roots of many tropical rainforest trees are shallow and concentrated near the surface in a mat only a few centimeters (an inch or so) thick. The root mat catches and absorbs almost all minerals released from leaves by decomposition. Swollen bases or braces called **buttress roots** hold the trees upright and aid in the extensive distribution of the shallow roots (FIG. 36-10b).

In swampy or tidal environments where the soil is flooded or waterlogged, some roots grow upward until they are above the high-tide level. Even though roots live in the soil, they still require oxygen for aerobic respiration. Flooded soils are depleted of oxygen, so these aerial “breathing” roots, known as **pneumatophores**, may assist in getting oxygen to the submerged roots (FIG. 36-10c). Pneumatophores, which also help anchor the plant, have a well-developed system of internal air spaces that is continuous with the submerged parts of the root, presumably allowing gas exchange. Black mangroves and white mangroves are examples of plants with pneumatophores.

Climbing plants and **epiphytes**, which are plants that grow attached to other plants, have aerial roots that anchor the plant to the bark, branch, or other surface on which they grow. Some epiphytes have aerial roots specialized for functions other than anchorage. Certain epiphytic orchids, for example, have photosynthetic roots (FIG. 36-10d). Epiphytic roots may absorb moisture as well.

Some parasitic epiphytes, such as mistletoe, have modified roots that penetrate the host-plant tissues and absorb water. Another plant that starts its life as an epiphyte is the strangler fig, which produces long roots that eventually reach the ground and anchor the plant (now a tree rather than an epiphyte) in the soil. The tree on which the strangler fig originally grew is often killed as the strangler fig grows around it, competing with it for light and other resources and crushing its secondary phloem.

CHECKPOINT 36.1

- What are the advantages of a taproot system? of a fibrous root system?
- If you were examining a cross section of a primary root of a flowering plant, how would you determine whether it was a eudicot or a monocot?

Key Point

The production of secondary tissues in roots, like that in stems, is the result of the activity of two lateral meristems: the vascular cambium and the cork cambium.

- 1 Tissues in primary root.
- 2 At onset of secondary growth, vascular cambium extends out to pericycle, forming continuous, noncircular loop.
- 3 Vascular cambium produces secondary xylem to its inside and secondary phloem to its outside.
- 4 Ring of vascular cambium gradually becomes circular. As vascular cambium continues to divide, epidermis, cortex, and primary phloem located in outer bark are torn apart.

Figure 36-9 Development of secondary vascular tissues in a primary root

The figures are not drawn to scale because of space limitations; the primary xylem is actually the same size in all four diagrams, but differences in scale make the xylem appear different sizes.

CONNECT In what directions does the stem vascular cambium produce secondary xylem and secondary phloem?

- By what mechanism(s) do water and dissolved minerals move through the symplast? the apoplast?
- In what way does the possession of a Casparian strip enable endodermal cells to carry out their essential function?
- How do the vascular cambium and the cork cambium of a herbaceous eudicot root function in the production of secondary tissues?
- What are the functions of each of the following: prop roots, buttress roots, and pneumatophores?

36.2 Root Associations and Interactions

LEARNING OBJECTIVE

- 6 List and describe two mutualistic relationships between roots and other organisms.

As roots of an individual plant extend through the soil, they often encounter the roots of related or unrelated plants. The nature of these interactions is largely unknown, but several

Figure 36-10 Specialized roots

studies suggest that roots are involved in complex ways, sometimes recognizing the identity of neighboring roots and modifying their growth accordingly. For example, wild

strawberry roots have been demonstrated to grow more vigorously when they encounter ground ivy roots; in contrast, root growth of ground ivy is inhibited by strawberry roots.

(a) LM of ectomycorrhizae, fungal associations that form a sheath around the root. The fungal hyphae penetrate the root between cortical cells but do not enter the cells.

(b) LM of endomycorrhizae, fungal associations in which the fungal hyphae penetrate root cells. The hyphae aid in delivering and receiving nutrients. Roots of most vascular plant species are colonized by endomycorrhizae.

(c) Fruiting body of the mycorrhizal fungus *Laccaria bicolor*, which is colonizing the roots of nearby Douglas fir seedlings.

Figure 36-11 Mycorrhizae

Mycorrhizae enhance plant growth by providing essential minerals to the roots.

Such root associations affect community dynamics in natural ecosystems and may affect the productivity of agricultural ecosystems.

The roots of terrestrial plant species may form *mutualistic*—that is, mutually beneficial—relationships with certain soil microorganisms: *mycorrhizal fungi* and *rhizobial bacteria*. These mutualistic relationships provide plants with access to essential minerals that are in limited supply in the soil.

Mycorrhizae facilitate the uptake of essential minerals by roots

Subterranean associations between roots and certain fungi, known as **mycorrhizae**, are found in virtually all terrestrial ecosystems. Mycorrhizae permit the transfer of materials (such as carbon compounds produced by photosynthesis) from roots to the fungus. At the same time, essential minerals, such as phosphorus, move from the fungus to the roots of the host plant. The threadlike body of the fungal partner extends into the soil, extracting minerals well beyond the reach of the plant's roots. In some mycorrhizae, the fungal mycelium encircles the root like a sheath; in others, the fungus penetrates cell walls of the root cortex and forms branching **arbuscules** (FIG. 36-11; also see Fig. 29-11).

The mycorrhizal relationship is an ancient one: some of the earliest known plant fossils (about 400 million years old) contain mycorrhizal fungi in the roots. The mycorrhizal relationship is mutually beneficial because when mycorrhizae are not present, neither the fungus nor the plant grows as well (see Fig. 29-19).

The hyphal network of mycorrhizae appears to interconnect the roots of different plant species in the community so that carbon compounds may flow from one plant to another through their mutual fungal partner.

The genome of an ectomycorrhizal fungus, *Laccaria bicolor*, has been sequenced, and scientists have identified many genes that code for *small secreted proteins* that may be involved in establishing the mutualistic relationship between the fungus and its plant partner (see Fig. 36-11c). For example, it has been learned that one such protein is secreted by the fungus in response to signals that diffuse from plant roots. The fungal

protein is then taken up by plant root cells by endocytosis and enters the nuclei where it affects the transcription of plant genes that promote the mutualistic mycorrhizal relationship.

Rhizobial bacteria fix nitrogen in the roots of leguminous plants

Certain nitrogen-fixing bacteria, collectively called **rhizobia**, form associations with the roots of leguminous plants such as clover, peas, and soybeans. **Nodules** (swellings) that house millions of the rhizobia develop on the roots (see Fig. 55-9). Evidence indicates that the rhizobial relationship evolved much later than the mycorrhizal relationship; unlike mycorrhizae, which infect most plant species, rhizobia almost exclusively infect plants of the legume family, which evolved about

70 million years ago. (A few other plant–bacteria associations that fix nitrogen have also evolved.)

As with mycorrhizae, the association between nitrogen-fixing bacteria and the roots of legumes is mutually beneficial. Bacteria receive photosynthetic products from plants while helping plants meet their nitrogen requirements by producing ammonia (NH_3) from atmospheric nitrogen.

For several decades, biologists have been studying the molecular basis of associations between plants and nitrogen-fixing bacteria. The two partners in this association use **cell signaling**—that is, a molecular dialogue back and forth between them—to establish contact and develop nodules. When soil contains a low level of nitrogen, legume roots secrete chemical attractants (flavonoids) toward which the rhizobial bacteria swim (FIG. 36-12).

Figure 36-12 Establishment of a relationship between rhizobial bacteria and leguminous plants

Much of the nitrogen produced by nitrogen-fixing bacteria in legume root nodules is transported in the vascular tissues throughout the plant body, including the seeds.

The initial signal molecules produced by rhizobial bacteria are called *nodulation factors*, or *nod factors*. These nod factors help root-hair cells in the roots of leguminous plants recognize the presence of the bacteria; recognition is the first step in the infection by rhizobia and the development of root nodules. The nod factor apparently attaches to a plant receptor on the root-hair plasma membrane. This attachment triggers a calcium-dependent **signal transduction** cascade within root cells that alters gene expression and metabolism, resulting in nodule formation. The plant hormone **cytokinin**, which triggers cell division (see Chapter 38), is involved in root nodule formation.

Some genes are involved in the initiation of both mycorrhizal and rhizobial associations Because both mycorrhizae and rhizobia infect plant roots, some biologists have hypothesized that the genes and signal transduction components involved in mycorrhizal relationships may have been recruited for the rhizobial relationships that evolved much later. There is experimental evidence to support this hypothesis. Some of the same genes that trigger infection and changes in root development to form rhizobial nodules are also involved in establishing mycorrhizal infections. Evidence includes several legume mutants that biologists have identified; these mutants lack the ability to develop nodules for rhizobial bacteria and cannot form mycorrhizal associations.

CHECKPOINT 36.2

- How are mycorrhizae and root nodules similar? How are they different?

36.3 The Soil Environment

LEARNING OBJECTIVES

- 7 Describe the roles of weathering, organisms, climate, and topography in soil formation.
- 8 List the four components of soil and give the ecological significance of each.
- 9 Describe how roots absorb positively charged mineral ions by the process of cation exchange.
- 10 Distinguish between macronutrients and micronutrients.
- 11 Explain the effects of mineral depletion and soil erosion on plant growth.

We now examine the soil environment in which most roots live. *Soil* is a relatively thin layer of Earth's crust that has been modified by the natural actions of weather, wind, water, and organisms. It is easy to take soil for granted. We walk on and over it throughout our lives but rarely stop to think about how important it is to our survival. Vast numbers and kinds of organisms colonize soil and depend on it for shelter and food. Most plants anchor themselves in soil, and from it they receive water and minerals. Almost all the elements essential for plant growth are obtained directly from the soil. With few

exceptions, plants cannot survive on their own without soil, and because we depend on plants for our food, neither could humans exist without soil.

Soils are generally formed from rock (called “parent material”) that is gradually broken down, or fragmented, into smaller and smaller particles by biological, chemical, and physical **weathering processes** (FIG. 36-13). Two important factors that work together in the weathering of rock are climate and organisms. When plant roots and other organisms living in the soil respire, they produce carbon dioxide (CO_2), which diffuses into the soil and reacts with soil water to form carbonic acid (H_2CO_3). Soil organisms such as lichens produce other kinds of acids. Recall from Chapter 29 that a lichen is a compound organism composed of one or more fungi and a phototroph (photosynthetic organism). These acids etch tiny cracks, or fissures, in the rock surface, and water then seeps into these cracks. If the parent material is located in a temperate climate, the alternate freezing and thawing of the water during winter causes the cracks to enlarge, breaking off small pieces of rock. Small plants can then become established and send their roots into the larger cracks, fracturing the rock further.

Topography, a region's surface features such as the presence or absence of mountains and valleys, is also involved in soil formation. Steep slopes often have little or no soil on them because the soil and rock are continually transported down the slopes by gravity. Runoff from precipitation tends to amplify erosion on steep slopes. Moderate slopes, in contrast, may encourage the formation of deep soils.

The disintegration of solid rock into finer and finer mineral particles in the soil takes an extremely long time, sometimes thousands of years. Soil forms constantly as the weathering of parent material beneath soil that is already formed continues to add new soil.

Soil comprises inorganic minerals, organic matter, air, and water

Soil comprises four distinct components: inorganic mineral particles (which make up about 45% of a typical soil), organic matter (about 5%), water (about 25%), and air (about 25%). The plants, animals, fungi, and microorganisms that inhabit soil interact with it, and minerals are continually cycled from the soil to organisms, which use them in their biological processes. When the organisms die, bacteria and other soil organisms decompose the remains, returning the minerals to the soil.

The inorganic mineral particles, which come from weathered rock, provide anchorage and essential minerals for plants as well as pore space for water and air. Because different rocks consist of different minerals, soils vary in mineral composition and chemical properties. Rocks rich in aluminum form acidic soils, for example, whereas rocks that contain silicates of magnesium and iron form soils that may be deficient in calcium, nitrogen, and phosphorus. Also, soils formed from the same kind of parent material may not develop in the same way because other factors, such as weather, topography, and organisms, differ.

Figure 36-13 The dynamics of soil formation

Weather, climate, topography, and organisms interact with Earth's crust to form soil, the material that supports plants and many other organisms on land.

The *texture*, or structural characteristic, of a soil is determined by the percentages (by weight) of the different-sized inorganic mineral particles—sand, silt, and clay—in it. The size assignments for sand, silt, and clay give soil scientists a way to classify soil texture. Particles larger than 2 mm in diameter, called gravel or stones, are not considered soil particles because they do not have any direct value to plants. The largest soil particles are called “sand” (0.02 to 2 mm in diameter); the medium-sized particles, “silt” (0.002 to 0.02 mm in diameter); and the smallest particles, “clay” (less than 0.002 mm in diameter). Sand particles are large enough to be seen easily with the eye, and silt particles (about the size of flour particles) can be seen with an ordinary light microscope. Most individual clay particles can be seen only under an electron microscope.

A soil's texture affects many of that soil's properties, in turn influencing plant growth. The clay component of a soil is particularly important in determining many of its characteristics because clay particles have the greatest surface area of all soil particles. If the surface areas of about 450 g (1 lb) of clay particles were laid out side by side, they would occupy 1 hectare (2.5 acres).

Each clay particle has predominantly negative electric charges on its outer surface that attract and reversibly bind **cations**, which are positively charged mineral ions such as potassium (K^+) and magnesium (Mg^{2+}). Because many

cations are essential for plant growth, cation adhesion to soil particles is an important aspect of soil fertility. Roots secrete protons (H^+), which are exchanged for other positively charged mineral ions adhering to the surface of soil particles, in a process known as **cation exchange**. These “freed” ions and the water that forms a film around the soil particles are absorbed by the plant's roots (**FIG. 36-14**).

In contrast, **anions**, which are negatively charged mineral ions, are repelled by the negative surface charges of clay particles and tend to remain in solution. Anions such as nitrate (NO_3^-) are often washed out of the root zone by water moving through the soil.

Soil always contains a mixture of different-sized particles, but the proportions vary from one soil to another. A *loam*, which is an ideal agricultural soil, has an optimum combination of different soil particle sizes: it contains approximately 40% each of sand and silt and about 20% of clay. Generally, the larger particles provide structural support, aeration, and permeability to the soil, whereas the smaller particles bind into aggregates, or clumps, and hold minerals and water. Soils with larger proportions of sand are not as desirable for most plants because they do not hold water and mineral ions well. Plants grown in such soils are more susceptible to drought and

mineral deficiencies. Soils with larger proportions of clay are also not desirable for most plants because they provide poor

Figure 36-14 Cation exchange

Negatively charged clay particles bind to positively charged mineral cations, holding them in the soil. Roots pump out protons (H^+), which are exchanged for the cations, facilitating their absorption.

drainage and often do not provide enough oxygen. Clay soils used in agriculture tend to compact, which reduces the number of soil spaces that can be filled by water and air.

A soil's organic matter consists of the wastes and remains of soil organisms The organic matter in soil is composed of litter (dead leaves and branches on the soil's surface); droppings (animal dung); and the dead remains of plants, animals, and microorganisms in various stages of decomposition. Organic matter is decomposed by microorganisms, particularly bacteria and fungi, that inhabit the soil. During decomposition, essential mineral ions are released into the soil, where they may be bound by soil particles or absorbed by plant roots. Organic matter increases the soil's water-holding capacity by acting much like a sponge. For this reason, gardeners often add organic matter to soils, especially sandy soils, which are naturally low in organic matter.

The partly decayed organic portion of the soil is referred to as **humus**. Humus, which is not a single chemical compound but a mix of many organic compounds, binds mineral ions and holds water. On average, humus persists in agricultural soil for about 20 years. Certain components of humus may persist in the soil for hundreds of years. Although humus is somewhat resistant to decay, a succession of microorganisms gradually reduces it to carbon dioxide, water, and minerals.

About 50% of soil volume is composed of pore spaces

Soil has numerous pore spaces of different sizes around and among the soil particles. Pore spaces occupy roughly 50% of a soil's volume and are filled with varying proportions of air and water. Both soil air and soil water are necessary to produce a moist but aerated soil that sustains plants and other soil-dwelling organisms. Water is usually held in the smaller pores, whereas air is found in the larger pores. After a prolonged rain, almost all the pore spaces may be filled with water, but water drains rapidly from the larger pore spaces, drawing air from the atmosphere into those spaces.

Soil air contains the same gases as atmospheric air, although they are usually present in different proportions. As a result of respiration by soil organisms, there is less oxygen and more carbon dioxide in soil air than in atmospheric air. (Aerobic respiration uses oxygen and produces carbon dioxide.) Among the important gases in soil are oxygen (O_2), required by soil organisms for aerobic respiration; nitrogen (N_2), used by nitrogen-fixing bacteria; and carbon dioxide (CO_2), involved in soil weathering.

Soil water originates as precipitation, which drains downward, or as groundwater (water stored in porous underground rock), which rises upward from the water table (the uppermost level of groundwater). Soil water contains low concentrations of dissolved minerals that enter the roots of plants when they absorb water. Water not bound to soil particles or absorbed by roots percolates (moves down) through soil, carrying dissolved minerals with it. The removal of dissolved materials

from soil by percolating water is called **leaching**. The deposition of leached material in the lower layers of soil is known as **illuviation**. Iron and aluminum compounds, humus, and clay are some illuvial materials that can gather in the subsurface portion of the soil. Some substances completely leach out of the soil because they are so soluble that they migrate down into the groundwater. It is also possible for water that is moving *upward* through the soil to carry dissolved materials with it.

Soil organisms form a complex ecosystem

A single teaspoon of fertile agricultural soil may contain millions of microorganisms, such as bacteria, fungi, algae, protozoa, as well as microscopic nematodes and other worms. Other organisms also colonize the soil ecosystem, including plant roots, earthworms, insects, moles, snakes, and groundhogs (**FIG. 36-15**). Most numerous in soil are bacteria, which number in the hundreds of millions per gram of soil. Scientists have identified about 170,000 species of soil organisms, but thousands remain to be identified. Little is known about the roles and interactions of soil organisms, in part because it is hard to study their activities under natural conditions.

Worms are some of the most important organisms living in soil. Earthworms, probably one of the most familiar soil inhabitants, ingest soil and obtain energy and raw materials by digesting humus. *Castings*, bits of soil that have passed through the gut of an earthworm, are deposited on or near the soil surface. In this way, minerals from deeper layers are brought to upper layers. Earthworm tunnels serve to aerate the soil, and the worms' waste products and corpses add organic material to the soil.

Ants live in the soil in enormous numbers, constructing tunnels and chambers that help aerate it. Members of soil-dwelling ant colonies forage on the surface for bits of food, which they carry back to their nests. Not all this food is eaten, however, and its eventual decomposition helps increase the organic matter in the soil. Many ants are also indispensable in plant reproduction because they bury seeds in the soil (discussed in Chapter 37).

Soil pH affects soil characteristics and plant growth

Acidity is measured using the pH scale, which extends from 0 (extremely acidic) through 7.0 (neutral) to 14.0 (extremely alkaline). The pH of most soils ranges from 4.0 to 8.0, but some soils are outside this range. The soil of the Pygmy Forest in Mendocino County, California, is extremely acidic (pH 2.8 to 3.9). At the other extreme, certain soils in Death Valley, California, have a pH of 10.5.

Plants are affected by soil pH, partly because the solubility of certain minerals varies with differences in pH. Soluble minerals can be absorbed by the plant, whereas insoluble forms cannot. At a low pH, for example, aluminum and manganese in soil water are more soluble than at higher pH and are sometimes absorbed by the roots in toxic concentrations. At

Soil provides most of the minerals found in plants

More than 90 naturally occurring elements exist on Earth, and more than 60 of them, including elements as common as carbon and as rare as gold, have been found in plant tissues. Not all these elements are essential for plant growth, however.

Nineteen elements have been found essential for most, if not all, plants (TABLE 36-1). Ten of them are required in fairly large quantities (greater than 0.05% dry weight) and are therefore known as **macronutrients**. Macronutrients are carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. The remaining nine **micronutrients** are needed in trace amounts (less than 0.05% dry weight) for normal plant growth and development. Micronutrients are chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum.

Four of the 19 elements—carbon, oxygen, hydrogen, and nitrogen—come directly or indirectly from soil water or from gases in the atmosphere. Carbon is obtained from carbon dioxide

in the atmosphere during photosynthesis. Oxygen is obtained from atmospheric oxygen (O_2) and water (H_2O). Water also supplies hydrogen to the plant. Plants absorb their nitrogen from the soil as ions of nitrogen salts, but the nitrogen in nitrogen salts ultimately comes from atmospheric nitrogen (N_2). The remaining 15 essential elements are obtained from the soil as dissolved mineral ions. Their ultimate source is the parent material from which the soil was formed.

Let us examine the main functions of essential elements. Carbon, hydrogen, and oxygen are found as part of the structure of all biologically important molecules, including lipids, carbohydrates, nucleic acids, and proteins. Nitrogen is part of proteins, nucleic acids, and chlorophyll.

Potassium, which plants use in fairly substantial amounts, is not found in a specific organic compound in plant cells. Instead, it remains as free K^+ and plays a key physiological role in maintaining the turgidity of cells because it is osmotically active. The presence of K^+ in cytoplasm causes water to pass through the plasma membrane into the cell by osmosis. Potassium is also involved in the opening of stomata.

Calcium plays a key structural role as a component of the middle lamella (the cementing layer between cell walls of adjacent plant cells). Calcium ions (Ca^{2+}) are also important

Figure 36-15 Diversity of life in fertile soil

Plants, algae, protozoa, fungi, bacteria, earthworms, flatworms, roundworms, insects, spiders and mites, and burrowing animals such as moles and groundhogs live in soil.

a higher pH, certain mineral salts essential for plant growth, such as calcium phosphate, become less soluble and thus less available to plants than at lower pH.

Soil pH also affects the leaching of minerals. An acidic soil has less ability than other soil to bind positively charged ions to it because the soil particles also bind the abundant protons (FIG. 36-16). As a result, certain mineral ions essential for plant growth, such as potassium (K^+), are leached more readily from acidic soil than other soil. The optimum soil pH for most plant growth is 6.0 to 7.0 because most essential minerals are available to plants in that pH range.

Acid precipitation, a type of air pollution in which sulfuric and nitric acids produced by human activities fall to the ground as acid rain, sleet, snow, or fog, can seriously decrease soil pH. Acid precipitation is one of several factors implicated in *forest decline*, the gradual deterioration, and often death, of trees that has been observed in many European and North American forests in recent decades. Forest decline may be partly the result of soil changes, such as leaching of essential cations, caused by acid precipitation. In central European forests that have experienced forest decline, for example, a strong correlation has been demonstrated between forest damage and soil chemistry altered by acid precipitation.

Figure 36-16 How acid alters soil chemistry

in physiological roles in plants, such as altering membrane permeability and as **second messengers** in various cell signaling responses (see Chapter 6).

Magnesium is critical for plants because it is part of the chlorophyll molecule. Phosphorus is a component of nucleic acids, phospholipids (part of cell membranes), and energy transfer molecules such as ATP. Sulfur is essential because it is found in certain amino acids and vitamins. Many plants accumulate silicon in their cell walls and intercellular spaces. Silicon enhances the growth and fertility of some species and may help reinforce cell walls.

Chlorine and sodium are micronutrients that help maintain cell turgor. In addition to this osmotic role, chloride (Cl⁻) and sodium (Na⁺) ions are essential for photosynthesis. Six of the micronutrients (iron, manganese, zinc, copper, nickel, and molybdenum) are associated with various plant enzymes, often as **cofactors**, and are involved in certain enzymatic reactions. Boron, present in cell walls, is also involved in nucleic acid metabolism and in cell growth.

How do biologists determine whether an element is essential? It is impossible to conduct mineral nutrition experiments by growing plants in soil because soil is too complex and contains too many elements. Therefore, nutritional studies require special methods. One of the most useful techniques to test whether an element is essential is **hydroponics**, which is the growing of plants in aerated water to which mineral salts have been added (**FIG. 36-17**). Hydroponics has commercial

Table 36-1 Functions of Elements Required by Most Plants

Element	Taken Up As	Major Functions
MACRONUTRIENTS		
Carbon	CO ₂	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Hydrogen	H ₂ O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Oxygen	O ₂ , H ₂ O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Nitrogen	NO ₃ ⁻ , NH ₄ ⁺	Component of proteins, nucleic acids, chlorophyll, and certain coenzymes
Potassium	K ⁺	Osmotic and ionic balance; opening of stomata; enzyme activator (for 40 enzymes)
Calcium	Ca ²⁺	In cell walls; involved in membrane permeability; enzyme activator; second messenger in metabolism
Magnesium	Mg ²⁺	In chlorophyll; enzyme activator in carbohydrate metabolism (phosphate transfer)
Phosphorus	HPO ₄ ²⁻ , H ₂ PO ₄ ⁻	In nucleic acids, phospholipids, ATP (energy transfer compound), and coenzymes
Sulfur	SO ₄ ²⁻	In certain amino acids and vitamins
Silicon	SiO ₃ ²⁻	In cell walls; increased resistance to pests and diseases; important primarily in grasses and sedges
MICRONUTRIENTS		
Chlorine	Cl ⁻	Ionic balance; involved in photosynthesis (production of oxygen)
Iron	Fe ²⁺ , Fe ³⁺	In enzymes and electron transport molecules involved in photosynthesis, respiration, and nitrogen fixation
Boron	H ₂ BO ₃ ⁻	In cell walls; involved in nucleic acid metabolism and in cell elongation
Manganese	Mn ²⁺	In enzymes involved in respiration and nitrogen metabolism; required for photosynthesis (production of oxygen)
Sodium	Na ⁺	Involved in photosynthesis (in C ₄ and CAM plants); substitutes for potassium in osmotic and ionic balance
Zinc	Zn ²⁺	In enzymes involved in respiration and nitrogen metabolism
Copper	Cu ⁺ , Cu ²⁺	In enzymes involved in photosynthesis
Nickel	Ni ²⁺	In enzymes (urease) involved in nitrogen metabolism; required by nitrogen-fixing bacteria
Molybdenum	MoO ₄ ²⁻	In enzymes involved in nitrogen metabolism

WHY IS IT USED? Using hydroponics, it is possible to grow plants in which only the mineral under investigation is absent from a nutrient solution. (It would be impossible to design such an experiment using soil.) Growing plants hydroponically in the absence of an essential mineral produces recognizable deficiency symptoms.

HOW IS IT DONE? The experimental and control plants are grown in two liquid solutions of mineral nutrients through which air is bubbled to allow the roots to respire. The liquid solution for the experimental plants contains all nutrient minerals known to be essential for plant growth except for one. The liquid solution for the control plants contains all known essential elements, including the one under study.

Figure 36-17 Plant nutritional studies in hydroponic growth systems

applications in addition to its scientific use. Lettuce is one of several crops that is grown hydroponically.

If biologists suspect that a particular element is essential for plant growth, they grow plants in a nutrient solution that contains all known essential elements *except* the one in question. If plants grown in the absence of that element cannot develop normally or complete their life cycle, the element may be essential. Additional criteria are used to confirm whether an element is essential. For example, it must be demonstrated that the element has a direct effect on the plant's metabolism and that the element is essential for a wide variety of plants.

Soil can be damaged by human mismanagement

Soil is a valuable natural resource on which humans depend for food. Many human activities generate or aggravate soil problems, including mineral depletion, soil erosion, and accumulation of salt.

Mineral depletion may occur in agricultural soils

In a natural ecosystem, the essential minerals removed from the soil by plants are returned when the plants or the animals that eat them die and are decomposed. An agricultural system disrupts this pattern of nutrient cycling when the crops

are harvested. Plant material containing minerals is removed from the nutrient cycle, and the harvested crops fail to decay and release their nutrients back to the soil. Over time, farmed soil inevitably loses its fertility, that is, its ability to produce abundant crops. Homeowners often mow their lawns and remove the clippings, similarly preventing decomposition and cycling of minerals that were in the grass blades.

The essential material (water, sunlight, or some essential element) that is in shortest supply usually limits plant growth. This phenomenon is sometimes called the concept of **limiting resources**. The three elements that are most often limiting resources for plants are nitrogen, phosphorus, and potassium. To sustain the productivity of agricultural soils, farmers periodically add fertilizers to depleted soils to replace the minerals that limit plant growth.

Soil erosion is the loss of soil from the land Water, wind, ice, and other agents cause **soil erosion**, the wearing away or removal of soil from the land. Water and wind are particularly effective in moving soil from one place to another. Rainfall loosens soil particles that can then be transported by moving water (**FIG. 36-18**). Wind loosens soil and blows it away, particularly if the soil is barren and dry. Soil erosion is a natural process that can be greatly accelerated by human activities.

Soil erosion is a national and international problem that does not make the headlines very often. The U.S. Department of Agriculture estimates that approximately 4.2 billion metric tons (4.6 billion tons) of topsoil are eroded each year from U.S. croplands and rangelands. Erosion causes a loss in soil fertility because essential minerals and organic matter that are a part of the soil are removed. As a result of these losses, the productivity of eroded agricultural soils declines, and more fertilizer must be used to replace the nutrients lost to erosion.

USDA/Natural Resources Conservation Service

Figure 36-18 Soil erosion in an open field

Removal of plant cover exposes bare soil to erosion in heavy rains. Precipitation can cause gullies to enlarge rapidly because they provide channels for the runoff of water.

Humans often accelerate soil erosion through poor soil management practices. Agriculture is not the only culprit; the removal of natural plant communities during surface mining, unsound logging practices (such as clear-cutting large areas of forest), and the construction of roads and buildings also accelerate erosion.

Soil erosion has an impact on other natural resources. Sediment that enters streams, rivers, and lakes degrades water quality and fish habitats. Pesticides and fertilizer residues in sediment may add pollutants to the water. Also, when forests are removed within the watershed of a hydroelectric power facility, accelerated soil erosion fills the reservoir behind the dam with sediment much faster than usual. This process reduces electricity production at that facility.

Sufficient plant cover reduces the amount of soil erosion: leaves and stems cushion the effect of rainfall, and roots help hold the soil in place. Although soil erosion is a natural process, abundant plant cover makes it negligible in many natural ecosystems.

Salt accumulates in soil that is improperly irrigated

Although irrigation improves the agricultural productivity of arid and semiarid lands, it sometimes causes salt to accumulate in the soil, a process called *salinization*. In a natural scenario, as a result of precipitation runoff, rivers carry dissolved salts away. Irrigation water, however, normally soaks into the soil and does not run off the land into rivers, so when water evaporates, the salt remains behind and accumulates in the soil. Salty soil results in a decline in productivity and, in extreme cases, renders the soil completely unfit for crop production.

Most plants cannot obtain all the water they need from salty soil because a water balance problem exists: water moves by osmosis *out* of plant roots and into the salty soil. Obviously, most plants cannot survive under these conditions (see Fig. 5-13). Plant species that thrive in saline soils have special adaptations that enable them to tolerate the high amount of salt. Black mangroves, for example, excrete excess salt through their leaves.

Unless they have been genetically selected to tolerate high salt, most crops are not productive in saline soil. Research on the molecular aspects of salt tolerance suggests that mutations in membrane transport proteins confer salt tolerance. Biologists genetically engineered a salt-tolerant variety of *Arabidopsis* to overexpress a single gene that codes for a sodium transport protein in the vacuolar membrane. These plants can store large quantities of sodium in their vacuoles, thereby tolerating saline soils.

CHECKPOINT 36.3

- What are the four components of soil, and how is each important to plants?
- How does cation exchange make mineral ions available for absorption by plant roots?
- In what ways do weathering processes convert rock into soil?
- What criteria are used to distinguish macronutrients from micronutrients?
- What are three ways in which human mismanagement can cause soil damage?

Summary: Focus on Learning Objectives

36.1 Root Structure and Function (page 763)

1 Distinguish between taproot and fibrous root systems.

- A **taproot system** has one main root (formed from the **radicle**) from which many lateral roots extend. A **fibrous root system** has several to many **adventitious** roots of the same size developing from the end of the stem. Lateral roots branch from these adventitious roots.

2 Compare cross sections of a primary eudicot root and a monocot root, and describe the functions of each tissue.

- Primary roots have an epidermis, ground tissues (cortex and, in certain roots, pith), and vascular tissues (xylem and phloem). Each root tip is covered by a **root cap**, a protective layer that covers the delicate root **apical meristem** and may orient the root so that it grows downward.
- **Epidermis** protects the root. **Root hairs**, short-lived extensions of epidermal cells, aid in absorption of water and dissolved minerals.
- **Cortex** consists of parenchyma cells that often store starch. **Endodermis**, the innermost layer of the cortex, regulates the movement of water and minerals into the root xylem. Cells of the endodermis have a **Casparian strip** around their radial and transverse walls that is impermeable to water and dissolved minerals.
- Pericycle, xylem, and phloem collectively make up the root's **stele**, or **vascular cylinder**. **Pericycle** gives rise to lateral roots and lateral meristems. **Xylem** conducts water and dissolved minerals; **phloem** conducts dissolved sugar.
- Xylem of a herbaceous eudicot root forms a solid core in the center of the root. The center of a monocot root often consists of pith surrounded by a ring of alternating bundles of xylem and phloem.

3 Trace the pathway of water and mineral ions from the soil through the various root tissues and distinguish between the symplast and apoplast.

- As water and dissolved mineral ions move from the soil into the root, they pass through the following tissues: root hair/epidermis → cortex → endodermis → pericycle → root xylem.
- Water and dissolved minerals move through the epidermis and cortex along one of two pathways: the **apoplast** (along the interconnected porous cell walls) or the **symplast** (from one cell's cytoplasm to the next through **plasmodesmata**).

4 Discuss the structure of roots with secondary growth.

- Roots of gymnosperms and woody eudicots develop secondary tissues (wood and bark). The production of secondary tissues is the result of the activity of two lateral meristems: the vascular cambium and cork cambium. The **vascular cambium** produces secondary xylem (wood) and secondary phloem (inner bark). The **cork cambium** produces **periderm** (outer bark).

5 Describe at least three roots that are modified to perform uncommon functions.

- **Prop roots** develop from branches or from a vertical stem and grow downward into the soil to help support certain plants in an upright position. **Buttress roots** are swollen bases or braces that support certain tropical rainforest trees that have shallow root systems. **Pneumatophores** are aerial "breathing" roots that may assist in getting oxygen to submerged roots.

36.2 Root Associations and Interactions (page 769)

6 List and describe two mutualistic relationships between roots and other organisms.

- **Mycorrhizae**, which are mutually beneficial associations between roots and soil fungi, enhance plant growth by providing essential minerals such as phosphorus to the roots.
- Root **nodules** are swellings that develop on roots of leguminous plants and house millions of **rhizobia** (nitrogen-fixing bacteria).

36.3 The Soil Environment (page 773)

7 Describe the roles of weathering, organisms, climate, and topography in soil formation.

- Factors influencing soil formation include parent material (type of rock), climate, organisms, the passage of time, and topography. Most soils are formed from parent material that is broken into smaller and smaller particles by **weathering processes**. Climate and organisms work together in weathering rock.
- Soil organisms such as plants, algae, fungi, worms, insects, spiders, and bacteria are important not only in forming soil but also in cycling minerals.
- Topography, a region's surface features, affects soil formation. Steep slopes have little or no soil on them, whereas moderate slopes often have deep soils.

8 List the four components of soil and give the ecological significance of each.

- Soil comprises inorganic minerals, organic matter, air, and water. Inorganic minerals provide anchorage and essential minerals for plants. Organic matter increases the soil's water-holding capacity and, as it decomposes, releases essential minerals into the soil. Soil air provides oxygen for soil organisms to use during aerobic respiration. Soil water provides water and dissolved minerals to plants and other organisms.

9 Describe how roots absorb positively charged mineral ions by the process of cation exchange.

- **Cations**, positively charged mineral ions, are attracted and reversibly bound to clay particles, which have predominantly negative charges on their outer surfaces. In **cation exchange**, roots secrete protons (H^+), which are exchanged for other positively charged mineral ions, freeing them into the soil water to be absorbed by roots.

10 Distinguish between macronutrients and micronutrients.

- Plants require 19 essential elements for normal growth. Ten elements are **macronutrients**: carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. Macronutrients are required in fairly large quantities.
- Nine elements are **micronutrients**: chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum. Micronutrients are needed in trace amounts.

11 Explain the effects of mineral depletion and soil erosion on plant growth.

- Mineral depletion may occur in soils that are farmed because the natural pattern of nutrient cycling is disrupted when crops are harvested (and not allowed to decompose into the soil).
- **Soil erosion** is the removal of soil from the land by agents such as water and wind. Erosion causes a loss in soil fertility because essential minerals and organic matter that are a part of the soil are removed.

Test Your Understanding

Know and Comprehend

- One main root, formed from the enlarging embryonic root, with many smaller lateral roots branching off it is (a) a fibrous root system (b) an adventitious root system (c) a tap-root system (d) a storage root system (e) a prop root system
- Root hairs (a) cover and protect the delicate root apical meristem (b) increase the absorptive capacity of roots (c) secrete a waxy cuticle (d) orient the root so that it grows downward (e) store excess sugars produced in the leaves
- Certain plants adapted to flooded soil produce aerial "breathing" roots known as (a) fibrous roots (b) pneumatophores (c) mycorrhizae (d) nodules (e) prop roots
- The waterproof region around the radial and transverse walls of endodermal cells is the (a) Casparian strip (b) pericycle (c) apoplast (d) symplast (e) pneumatophore
- The apoplast is (a) a layer of cells that surround the vascular region in roots (b) the layer of cells just inside the endodermis (c) a system of interconnected plant cell walls through which water moves (d) the central cylinder of the root that comprises the vascular tissues (e) a continuum of cytoplasm of many cells, all connected by plasmodesmata
- Plants obtain positively charged mineral ions from clay particles in the soil by cation exchange, in which (a) roots passively absorb the positively charged mineral ions (b) mineral ions flow freely along porous cell walls (c) roots secrete protons, which free other positively charged mineral ions to be absorbed by roots (d) the Casparian strip effectively blocks the passage of water and mineral ions along the endodermal cell wall (e) a well-developed system of internal air spaces in the root allows both gas exchange and cation exchange
- The cell layer from which lateral roots originate is the (a) epidermis (b) cortex (c) endodermis (d) pericycle (e) vascular cambium
- Mutually beneficial associations between certain soil fungi and the roots of most plant species are called (a) mycorrhizae (b) pneumatophores (c) nodules (d) rhizobia (e) humus
- Which of the following statements about soil is *true*? (a) pore spaces are always filled with about 50% air and 50% water (b) a single teaspoon of fertile agricultural soil may contain up to several hundred living microorganisms (c) the texture of a soil is determined by the soil's pH (d) a soil's organic matter includes litter, droppings, and the dead remains of plants, animals, and microorganisms (e) soil formation is unaffected by a region's climate or topography
- Carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon are collectively known as (a) micronutrients (b) microvilli (c) micronuclei (d) macronuclei (e) macronutrients

Apply and Analyze

- VISUALIZE** Draw a simple sketch illustrating the relationships of the following in a cross section of a primary root: remnant of primary xylem, vascular cambium, secondary phloem, secondary xylem, and periderm.

Evaluate and Synthesize

- A mesquite root is found penetrating a mine shaft about 46 m (150 ft) below the surface of the soil. How could you determine *when* the root first grew into the shaft? (*Hint*: Mesquite is a woody plant.)

- You are given a plant part that was found growing in the soil and are asked to determine whether it is a root or an underground stem. How would you identify the structure without a microscope? with a microscope?
- Explain why, once secondary growth has occurred, that portion of the root is no longer involved in absorption. Where does absorption of water and dissolved minerals occur in plants that have roots with secondary growth?
- EVOLUTION LINK** A barrel cactus that is 60 cm tall and 30 cm in diameter has roots more than 3 m long. However, all the plant's roots are found in the soil at a depth of 5 to 15 cm. What possible adaptive value does such a shallow root system confer on a desert plant?
- SCIENCE, TECHNOLOGY, AND SOCIETY** What is the agricultural value of research to understand the control of root hair development? of the interactions leading to the development of mycorrhizal associations?
- INTERPRET DATA** When soil has become polluted with hazardous materials such as heavy metals, it is sometimes cost-effective to construct an artificial marsh around the site. Water is pumped through the contaminated soil, picking up the hazardous material, and then the water is passed through the artificial wetland. In one experiment, scientists compared the effectiveness of the roots of two different marsh plants (cattails and common reeds) in absorbing the heavy metal selenium. Which plant's roots removed the most selenium? What should be done to the plants after they have absorbed selenium?

37 Reproduction in Flowering Plants

KEY CONCEPTS

- 37.1** The flower is the site of sexual reproduction in angiosperms. A typical flower consists of four whorls: sepals, petals, stamens, and carpels.
- 37.2** Pollen grains are transported to stigmas by a variety of agents, such as animals and wind.
- 37.3** Double fertilization results in a plant embryo and endosperm. The seed is a mature ovule, and the fruit is a mature ovary.
- 37.4** Following a period of dormancy, a seed germinates, or sprouts. The young seedling becomes anchored in the ground and begins to photosynthesize.
- 37.5** Many vegetative organs (roots, stems, and leaves) are modified for asexual reproduction.
- 37.6** Sexual reproduction in flowers results in genetic variability in the offspring, whereas asexual reproduction in vegetative structures generally results in individuals that are genetically identical.

PHOTO: Longleaf starwort flower. This plant (*Stellaria longifolia*) is native to northern Europe and North America. Joel Sartore/Getty Images

Flowering plants, or **angiosperms**, include about 300,000 species and are the largest, most successful group of plants. You may have admired flowers for their fragrances as well as their appealing colors and varied shapes (see photograph). The biological function of flowers is sexual reproduction. Their colors, shapes, and fragrances increase the likelihood that pollen grains, which produce sperm cells, will be carried from one plant to another. Sexual reproduction in plants includes *meiosis* and the fusion of reproductive cells: egg and sperm cells, collectively called **gametes**. The union of gametes, called fertilization, occurs within the flower's ovary.

Sexual reproduction offers the advantage of new gene combinations, not found in either parent, that may make an individual plant better suited to its environment. These new combinations result from the crossing-over and independent assortment of chromosomes that occur during *meiosis*, before the production of egg and sperm cells (see Chapter 11).

Many flowering plants also reproduce asexually. Asexual reproduction often does not involve the formation of flowers, seeds, and fruits. Instead, offspring generally form when a vegetative organ (such as a stem, root, or leaf) expands, grows, and then becomes separated from the rest of the plant, often by the death of tissues. Because asexual reproduction requires only one parent and no *meiosis* or fusion of gametes occurs, the offspring of asexual reproduction are virtually genetically identical to one another and to the parent plant.¹

This chapter examines both sexual and asexual reproduction in flowering plants, including floral adaptations that are important in

¹ Somatic mutations can result in some variability among asexually derived offspring.

pollination, seed and fruit structure and dispersal, germination and early growth, and several kinds of asexual reproduction. We conclude with a discussion of the evolutionary advantages and disadvantages of sexual and asexual reproduction.

37.1 The Flowering Plant Life Cycle

LEARNING OBJECTIVES

- 1 Describe the functions of each part of a flower.
- 2 Identify where eggs and pollen grains are formed within the flower.

In Chapters 27 and 28 you learned that angiosperms and other plants undergo a cyclic **alternation of generations** in which they spend a portion of their life cycle in a multicellular haploid stage and a portion in a multicellular diploid stage. The haploid portion, called the **gametophyte generation**, gives rise to gametes by mitosis. When two gametes fuse during **fertilization**, the diploid portion of the life cycle, called the **sporophyte generation**, begins. The sporophyte generation produces haploid spores by meiosis. Each spore has the potential to give rise to a gametophyte plant, and the cycle continues.

In flowering plants the diploid sporophyte generation is larger and nutritionally independent. The haploid gametophyte generation, which is located in the flower, is microscopic and nutritionally dependent on the sporophyte. We say more about alternation of generations in flowering plants after our discussion of the role of flowers as reproductive structures. (It may be helpful for you to review Figure 28-13, which shows the main stages in the flowering plant life cycle.)

Flowers develop at apical meristems

How does a plant “know” that it is time to start forming flowers? Correct timing in the switch from vegetative to reproductive development is crucial to ensure reproductive success. A variety of environmental cues, such as temperature and day length, ensure proper timing, and different species are adapted to respond to distinct environmental cues. These environmental signals interact with a variety of plant hormones and developmental pathways.

In recent years some biologists have focused on the molecular aspects of developmental pathways that initiate flowering in plants such as the model organism *Arabidopsis*. When environmental conditions induce flowering, many genes are activated or inactivated. For example, one gene, the *Flowering Locus C* (*FLC*) gene, codes for a *transcription factor* that represses flowering. (You may recall from Chapter 14 that transcription factors are DNA-binding proteins that regulate the synthesis of RNA from a DNA template.) Another gene, called *Flowering Locus D* (*FLD*), codes for a protein that removes acetyl groups from histones in the chromatin where the *FLC* gene is located. When deacetylation occurs, the *FLC* gene is not transcribed

(i.e., the repressive transcription factor is not produced), and the shoot apical meristem undergoes a transition from vegetative growth to reproductive growth. It is intriguing that the plant *FLD* protein is homologous to a mammalian protein that also removes acetyl groups from chromatin.

Other genes are also involved in the initiation of flowering, and this area remains a focus of active research interest. In Chapter 38 we discuss the initiation of flowering further.

Each part of a flower has a specific function

Flowers are reproductive shoots, usually consisting of four kinds of organs—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk (**FIG 37-1**; also see Fig. 28-11). In flowers with all four organs, the normal order of whorls from the flower’s periphery to the center (or from the flower’s base upward) is as follows:

sepals → petals → stamens → carpels

The tip of the stalk enlarges to form a **receptacle** on which some or all of the flower parts are borne. All four floral parts are important in the reproductive process, but only the stamens (the “male” organs) and carpels (the “female” organs) participate directly in sexual reproduction; sepals and petals are sterile.

Sepals, which constitute the outermost and lowest whorl on a floral shoot, cover and protect the flower parts when the flower is a bud. Sepals are leaflike in shape and form and are often green. Some sepals, such as those in lily flowers, are colored and resemble petals (**FIG. 37-2**). The collective term for all the sepals of a flower is **calyx**.

The whorl just inside and above the sepals consists of **petals**, which are broad, flat, and thin (like sepals and leaves) but widely varied in shape and frequently brightly colored, which attracts pollinators. Petals play an important role in ensuring that sexual reproduction will occur. Sometimes petals fuse to form a tube or other floral shape. The collective term for all the petals of a flower is **corolla**.

Just inside and above the petals are the **stamens**, the male reproductive organs. Each stamen has a thin stalk, called a **filament**, at the top of which is an **anther**, a saclike structure in which **pollen grains** form. For sexual reproduction to occur, pollen grains must be transferred from the anther to the female reproductive structure (the carpel), usually of another flower of the same species. At first, each pollen grain consists of two cells surrounded by a tough outer wall. One cell, the *generative cell*, divides mitotically to form two nonflagellate male gametes, known as *sperm cells*. The other cell, the *tube cell*, produces a **pollen tube** through which the sperm cells travel to reach the ovule.

One or more **carpels**, the female reproductive organs, are located in the center or top of most flowers. Carpels bear **ovules**, which are structures with the potential to develop into seeds. The carpels of a flower may be separate or fused into a single structure. The female part of the flower, often called a **pistil**, may be a single carpel (a *simple pistil*) or a group of

Figure 37-1 Floral structure

An *Arabidopsis* flower has four sepals (two are shown in this cutaway view), four petals (two are shown), six stamens, and one long pistil. Four of the stamens are long, and two are short (two long and two short are shown). Pollen grains develop within sacs in the anthers. In *Arabidopsis*, the compound pistil consists of two carpels, each containing numerous ovules.

fused carpels (a *compound pistil*) (see Fig. 28-12). Each pistil has three sections: a **stigma**, on which the pollen grains land; a **style**, a necklike structure through which the pollen tube grows; and an **ovary**, a juglike structure that contains one or more ovules and can develop into a fruit.

Considerable variation in flower structure occurs from one species to another, but flower structure is virtually constant within a given species. For that reason, flower structure is important in plant identification, and if flowers are present, flowering plant species are easy to evaluate in the field.

Female gametophytes (embryo sacs) are produced in the ovary, male gametophytes in the anther Before we proceed, it may be helpful to relate the stages in alternation of generations to floral structure. As discussed in Chapters 27 and 28, angiosperms and certain other plants are heterosporous and produce two kinds of spores: megaspores and microspores (FIG. 37-3).

Each young ovule within an ovary contains a diploid cell, the *megasporocyte*, which undergoes meiosis to produce four haploid **megaspores**. Three of them usually disintegrate, and the fourth, the functional megaspore, divides mitotically to produce a multicellular **embryo sac**, which is the *female gametophyte*. The embryo sac, which is embedded in the ovule, typically contains seven cells with eight haploid nuclei. Six of these cells, including the egg cell (the female gamete), contain a single nucleus each; a large central cell has two nuclei, called **polar nuclei**.

Figure 37-2 Lily flowers

In lily (*Lilium*), the three sepals and three petals are similar in size and color.

Key Point

In alternation of generations in flowering plants, the female and male gametophytes are microscopic and nutritionally dependent on the sporophyte plant.

The egg and both polar nuclei participate directly in fertilization.

Pollen sacs within the anther contain numerous diploid cells called *microsporocytes*, each of which undergoes meiosis to produce four haploid cells called **microspores**. Each microspore divides mitotically to produce an immature male gametophyte, also called a pollen grain, that consists of two cells: the tube cell and the generative cell. The pollen grain becomes mature when its generative cell divides to form two nonmotile sperm cells.

CHECKPOINT 37.1

- How do petals differ from sepals? How are they similar?
- How do stamens differ from carpels? How are they similar?
- **CONNECT** What are the female gametophytes of flowering plants, and where are they formed?
- **CONNECT** What are the male gametophytes of flowering plants, and where are they formed?

37.2 Pollination

LEARNING OBJECTIVES

- 3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, and bats).
- 4 Define *coevolution* and give examples of ways that plants and their animal pollinators have affected each other's evolution.

Before fertilization can occur, pollen grains must travel from the anther (where they form) to the stigma. The transfer of pollen grains from anther to stigma is known as **pollination**. Plants are *self-pollinated* if pollination occurs within the same flower or a different flower on the same individual plant. When pollen grains are transferred to a flower on another individual of the same species, the plant is *cross-pollinated*. Flowering plants accomplish pollination in a variety of ways. Beetles, bees, flies, butterflies, moths, wasps, and other insects pollinate many flowers. Animals such as birds, bats, snails, and small nonflying mammals (rodents, primates, and marsupials) also pollinate plants. Wind is an agent of pollination for certain flowers; and water, for a few aquatic flowers.

Many plants have mechanisms that prevent self-pollination

In plant sexual reproduction, the two gametes that unite to form a zygote may be from the same parent or from two different parents. The combination of gametes from two different parents increases the variation in offspring, and this variation may confer a selective advantage. Some offspring, for example, may be able to survive environmental changes better than either parent can.

Evolution has resulted in a variety of mechanisms that prevent self-pollination and thus prevent **inbreeding**, which is the mating of genetically similar individuals. Inbreeding can increase the concentration of harmful genes in the offspring. Some plants, such as asparagus and willow, have separate male and female individuals; the male plants have staminate flowers that lack carpels, and the female plants have pistillate flowers that lack stamens. Other species have flowers with both stamens and pistils, but the pollen is shed from a given flower either before or after the time when the stigma of that flower is receptive to pollen. These characteristics promote **outbreeding** (also called *outcrossing*), which is the mating of dissimilar individuals.

Many species have genes for **self-incompatibility**, a genetic condition in which the pollen is ineffective in fertilizing the same flower or other flowers on the same plant. In other words, an individual plant can identify and reject its own pollen. Genes for self-incompatibility usually inhibit the growth of the pollen tube in the stigma and style, thereby preventing delivery of sperm cells to the ovules. Self-incompatibility, which is more common in wild species than in cultivated plants, ensures that reproduction occurs only if the pollen comes from a genetically different individual.

In plants such as oilseed rape, self-incompatibility is based on a high degree of variation at a particular locus called the *S* locus; the many alleles at this locus are designated S_1 , S_2 , S_3 , S_4 , and so on. Here is an example of how the *S* locus blocks self-fertilization. A plant with the genotype S_1S_2 produces pollen grains that land on a stigma of another plant with the genotype S_1S_3 . In this case, the presence of the S_1 allele in both the pollen and stigma triggers a self-recognition signaling cascade in surface cells of the stigma. As a result, the stigma cells do not undergo changes that allow the pollen grain to grow a pollen tube. Therefore, fertilization does not occur.

The molecular basis of self-incompatibility in *Arabidopsis* and related plants is an area of active scientific interest. *Arabidopsis* can self-pollinate. Biologists have determined that the genes involved in self-incompatibility and outcrossing exist in *Arabidopsis* but have undergone mutations so that they are no longer functional. Thus, it appears that self-incompatibility in these plants is the ancestral condition.

Flowering plants and their animal pollinators have coevolved

Animal pollinators and the plants they pollinate have had such close, interdependent relationships over time that they have affected the evolution of certain physical and behavioral features in one another. **Coevolution** describes such reciprocal adaptation, in which two species interact so closely that they become increasingly adapted to each other as they each undergo evolutionary change by *natural selection*. We now examine some of the features of flowers and their pollinators that may be the products of coevolution.

Flowers pollinated by animals have various features to attract their pollinators, including showy petals (a visual attractant) and scent (an olfactory attractant) (**FIG. 37-4** and **TABLE 37-1**). One reward for the animal pollinator is food. Pollen grains are a protein-rich food for many animals. As they move from flower to flower searching for food, pollinators inadvertently carry along pollen grains on their body parts, helping the plants reproduce sexually.

Some flowers produce nectar, a sugary solution in special floral glands called *nectaries*. Pollinators use nectar, which is also rich in amino acids, alkaloids, and other floral chemicals, as an energy-rich food. Some nectars contain alkaloids such as nicotine to prevent animal pollinators from drinking all the nectar in a single visit. (Nicotine is poisonous.) Thus, pollinators are encouraged to visit multiple flowers, and each flower has multiple pollinator visitors.

Biologists estimate that insects pollinate about 70% of all flowering plant species. Bees are particularly important as pollinators of crop plants. Crops pollinated by bees provide about 30% of human food. Plants pollinated by insects often have blue or yellow petals. The insect eye does not see color the same way the human eye does. Most insects see well in the violet, blue, and yellow range of visible light but do not perceive red as a distinct color. So, flowers pollinated by insects are not usually red. Insects also see in the ultraviolet range,

(h) A lesser long-nosed bat (*Leptonycteris curasoae*) obtains nectar from a cardon cactus flower (*Pachycereus*) and transfers pollen as it moves from flower to flower. Bats pollinate several hundred species of plants.

Figure 37-4 Flowers and their animal pollinators

Table 37-1 Floral Characteristics Associated with Various Animal Pollinators

Animal Pollinator	Common Flower Color	Scent	Pollinator Reward	Time of Flowering
Bee	Yellow, blue, purple	Strong, floral	Nectar, pollen	Day
Butterfly	Red, pink	Weak, floral	Nectar	Day
Moth	White	Strong, sweet	Nectar	Dusk, night
Carrion fly	Reddish-brown, purple	Strong, rotten	No reward	Day, night
Beetle	Green, white	Strong, various scents	Nectar, pollen	Day, night
Bird	Red, pink	No scent	Nectar	Day
Bat	White	Strong, musklike or sweet	Nectar, pollen	Night

wavelengths that are invisible to the human eye. Insects see ultraviolet radiation as a color called *bee's purple*. Many flowers have dramatic UV markings that may or may not be visible to humans but that direct insects to the center of the flower where the pollen grains and nectar are.

Insects have a well-developed sense of smell, and many insect-pollinated flowers have a strong scent that may be pleasant or foul to humans. The carrion plant, for example, is pollinated by flies and smells like the rotting flesh in which flies lay their eggs. As flies move from one reeking flower to another looking for a place to lay their eggs, they transfer pollen grains.

Birds such as hummingbirds are important pollinators. Flowers pollinated by birds are usually red, orange, or yellow because birds see well in this range of visible light. Because most birds do not have a strong sense of smell, bird-pollinated flowers usually lack a scent.

Bats, which feed at night and do not see well, are important pollinators, particularly in the tropics. Bat-pollinated flowers bloom at night and have dull white petals and a strong nighttime output of scent that usually smells like fermented fruit. Nectar-feeding bats are attracted to the flowers by the scent; they lap up the nectar with their long, extendible tongues. As they move from flower to flower, they transfer pollen grains. An unusual adaptation that encourages pollination by bats has evolved in the tropical vine *Mucana holtonii*. When the pollen in a given flower is mature, a concave petal lifts up. The petal bounces the echo from the bat's echo-locating calls back to the bat, helping it find the flower.

Specialized features such as petals, scent, and nectar to attract pollinators have coevolved with adaptations of animal pollinators. Specialized body parts and behaviors adapted animals to aid pollination as they obtain nectar and pollen grains as a reward. For example, coevolution has selected for bumblebees' hairy bodies, which catch and hold the sticky pollen grains for transport from one flower to another.

Coevolution may have led to the long, curved beaks of the 'iwi, one of the Hawaiian honeycreepers, that inserts its beak into tubular flowers to obtain nectar (see Figs. 1-13b and 20-18). The long, tubular corolla of the flowers that 'iwis visit probably also came about through coevolution. During the 20th century, some of the tubular flower species (such as lobelias) became rare, largely as a result of grazing by nonnative cows and feral goats, and about 25% of lobelia species have become extinct. The 'iwi now feeds largely on the flowers of the 'ohi'a tree, which lacks petals, and the

'iwi bill appears to be adapting to this change in feeding preference. Comparison of the bills of 'iwi museum specimens collected in 1902 with the bills of live birds captured in the 1990s showed that 'iwi bills were about 3% shorter in the 1990s than in 1902.

Plants and the behavior of their animal pollinators have coevolved, sometimes in bizarre and complex ways. The flowers of certain orchids (*Ophrys*) resemble female bees in coloring and shape. The unpollinated flowers secrete a scent similar to that produced by female bees, and the males are irresistibly attracted to it. The resemblance between *Ophrys* flowers and female bees is so strong that male bees mount the flowers and try to copulate with them. During this *pseudocopulation*, a pollen sac usually attaches to the back of the bee. When the frustrated bee departs and tries to copulate with another orchid flower, pollen grains are transferred to that flower. Interestingly, once a flower has been pollinated, it emits a scent like that released by female bees that have already mated. Male bees have no interest in visiting flowers that have been pollinated (just as they lose interest in female bees that have already been inseminated).

Biologists think that hummingbird-pollinated flowers arose from insect-pollinated flowers many times during the course of flowering plant evolution. In one experiment researchers demonstrated that a single gene mutation affecting petal color could have been partly responsible for the pollinator shift that resulted in the evolution of two closely related species, *Mimulus lewisii* and *Mimulus cardinalis*, from their insect-pollinated common ancestor (FIG. 37-5).

Some flowering plants depend on wind to disperse pollen

Some flowering plants, such as grasses, ragweed, maples, and oaks, are pollinated by wind. Wind-pollinated plants produce many small, inconspicuous flowers (FIG. 37-6). They do not produce large, colorful petals, scent, or nectar. Some have large, feathery stigmas, presumably to trap wind-borne pollen grains. Because wind pollination is a hit-or-miss affair, the likelihood of a particular pollen grain landing on a stigma of the same species of flower is slim. Wind-pollinated plants produce large quantities of pollen grains, which increase the likelihood that some pollen grains will land on the appropriate stigma.

Key Experiment

Can a single gene mutation in flower color affect animal pollinators?

HYPOTHESIS: If flower color is changed by a mutation, pollinator preferences for the resulting flower may change.

EXPERIMENT: *Mimulus lewisii* has violet-pink flowers and is pollinated by bumblebees; the closely related *M. cardinalis* has orange-red flowers and is pollinated by hummingbirds. Alleles at the same locus in both species affect flower color.

Researchers transferred the allele for orange-red flowers from *M. cardinalis* to *M. lewisii*, which then produced yellow-orange petals. They also transferred the allele for pink flowers from *M. lewisii* to *M. cardinalis*, which then produced dark pink petals.

Wild-type *M. lewisii*

Altered *M. lewisii*

Wild-type *M. cardinalis*

Altered *M. cardinalis*

RESULTS AND CONCLUSION: The modified *M. lewisii* flowers were yellow-orange in color and had 68 times as many hummingbird visits as the unaltered *M. lewisii* flowers. The modified *M. cardinalis* flowers had dark pink petals and were visited by 74 times as many bumblebees as the unaltered *M. cardinalis* flowers. Thus, a single mutation in a gene for flower color resulted in a shift in animal pollinators.

Figure 37-5 Studying how pollinator preferences may have evolved

Biologists from the University of Washington and Michigan State University used monkey flowers to determine if a single gene mutation would have any effect on animal pollinators.

PREDICT What other floral traits in monkey flowers are likely to influence whether they are pollinated by hummingbirds or bumblebees?

Dr. Jeremy Burgess/Science Source

Figure 37-6 Wind pollination

Each cluster of male oak flowers (*Quercus*) dangles from a tree branch and sheds a shower of pollen when the wind blows. These flowers lack petals.

CHECKPOINT 37.2

- **PREDICT** A flower has yellow petals, a pleasant scent, and sugary nectar. How is it probably pollinated?
- **PREDICT** A flower has small, inconspicuous flowers without petals, a scent, or nectar. How is it probably pollinated?
- Give three examples in which the relationship of a plant and its pollinators demonstrates coevolution.

37.3 Fertilization and Seed and Fruit Development

LEARNING OBJECTIVES

- 5 Distinguish between pollination and fertilization.
- 6 Trace the stages of embryo development in flowering plants and list and define the main parts of seeds.
- 7 Explain the relationships among ovules, ovaries, seeds, and fruits.
- 8 Distinguish among simple, aggregate, multiple, and accessory fruits.

After pollen grains have been transferred from anther to stigma, the tube cell—one of the two cells in the pollen grain—grows a thin pollen tube down through the style and into an ovule in the ovary. How does the pollen tube “know” where

to grow? Scientists have identified molecular signals from the synergid cells located adjacent to the egg that guide the growing pollen tube toward the ovule. Two attracting signals (called LUREs), both small polypeptides, have been studied in wish-bone flowers (*Torenia fournieri*), and there are ongoing investigations to detect others and to understand their mechanisms of action.

Once a pollen tube penetrates the ovule, the attracting signals are no longer produced. As a result, only one pollen tube enters each embryo sac. The second cell within the pollen grain divides to form two male gametes (the sperm cells), which move down the pollen tube and enter the ovule (FIG. 37-7).

A unique double fertilization process occurs in flowering plants

The egg within the ovule unites with one of the sperm cells, forming a zygote (fertilized egg) that develops into an embryonic plant contained in the future seed. The two polar nuclei

in the central cell of the ovule fuse with the second sperm cell to form the first cell of the triploid ($3n$) **endosperm**, the tissue with nutritive and hormonal functions that surrounds the developing embryonic plant in the seed. This process, in which two separate cell fusions occur, is called **double fertilization**. It is, with few exceptions, unique to flowering plants. (A type of double fertilization has been reported in two gymnosperm species, *Ephedra nevadensis* and *Gnetum gnemon*.)

After double fertilization, the ovule develops into a *seed*, and the surrounding ovary develops into a *fruit* (see discussion in Chapter 28).

Embryonic development in seeds is orderly and predictable

Flowering plants package a young plant embryo, complete with stored nutrients, in a compact **seed**, which develops from the ovule after fertilization. The nutrients in seeds are not only used by germinating plant embryos but also eaten by animals, including humans. Development of the embryo and endosperm following fertilization is possible because of the constant flow of nutrients into the developing seed from the parent plant.

Cell divisions of the fertilized egg to form a multicellular embryo proceed in several ways in flowering plants. We describe eudicot embryonic development; monocot embryonic development is similar in the early stages.

Figure 37-7 Pollination, pollen tube growth, and double fertilization

Figure 37-8 Embryonic development in shepherd's purse (*Capsella bursa-pastoris*)
The ovule is shown apart from the ovary in parts 1 through 5.

The two cells (basal cell and apical cell) that are formed as a result of the first division of the fertilized egg establish *polarity*, or direction, in the embryo. The large *basal cell* (located toward the outside of the ovule) typically develops into a **suspensor**, an embryonic tissue that anchors the developing embryo and aids in nutrient uptake from the endosperm. The *apical cell* (toward the inside of the ovule) develops into the plant embryo. Scientists are currently studying molecular differences between the apical cell and basal cell to determine the initial molecular signals that are involved in establishing polarity.

Initially, the apical cell divides to form a small cluster of cells, called a *proembryo* (FIG. 37-8). As cell division continues, a sphere of cells, often called a *globular embryo*, develops. Cells begin to develop into specialized tissues during this stage. When the eudicot embryo starts to develop its two cotyledons

(seed leaves), it has two lobes and resembles a heart (the *heart stage*). During the *torpedo stage*, the embryo continues to grow as the cotyledons elongate. As the embryo enlarges, it often curves back on itself and crushes the suspensor.

The mature seed contains an embryonic plant and storage materials

A mature seed contains an embryonic plant and food (stored in the cotyledons or endosperm), surrounded by a tough, protective **seed coat** derived from the **integuments**, which are the outermost layers of an ovule. The seed, in turn, is enclosed within a fruit.

The mature embryo within the seed consists of a short embryonic root, or **radicle**; an embryonic shoot; and one or two seed leaves, or **cotyledons** (FIG. 37-9). Monocots have a

Figure 37-9 Seed structure

A bean seed has been dissected—its seed coat and one of its two cotyledons were removed—to show the radicle, hypocotyl, remaining cotyledon, and plumule with its foliage leaf at the shoot apex. This particular seed had begun germinating, so its radicle is larger than in an ungerminated seed.

single cotyledon, whereas eudicots have two. The short portion of the embryonic shoot connecting the radicle to one or two cotyledons is the **hypocotyl**. The shoot apex, or terminal bud, located above the point of attachment of the cotyledon(s) is the **plumule**. After the radicle, hypocotyl, cotyledon(s), and plumule have formed, the young plant's development is arrested, usually by desiccation (drying out) or **dormancy** (a temporary state of arrested physiological activity). When conditions are right for continuing the developmental program, the seed **germinates**, and the embryo resumes growth.

Many seeds are known to remain dormant for a decade or so. Only a few instances of germination after hundreds of years of dormancy have been scientifically documented. In 2008, a team of biologists from Israel and Switzerland successfully germinated a date seed (*Phoenix dactylifera*) that was radiocarbon dated at about 2000 years old. Before this report, the oldest documented instance of germination was a 1200-year-old lotus seed (*Nelumbo nucifera*).

Because the embryonic plant is nonphotosynthetic, it must be nourished during germination until it becomes photosynthetic and therefore self-sufficient. The cotyledons of many plants function as storage organs and become large, thick, and fleshy as they absorb the food reserves (starches, oils, and proteins) initially produced as endosperm. Seeds that store nutrients in cotyledons have little or no endosperm at maturity. Examples of such seeds are peas, beans, squashes, sunflowers, and peanuts. Other plants—wheat and corn, for example—have thin cotyledons that function primarily to help the young plant digest and absorb food stored in the endosperm.

Fruits are mature, ripened ovaries

After double fertilization takes place within the ovule, the ovule develops into a seed, and the ovary surrounding it develops into a **fruit**. For example, a pea pod is a fruit, and the peas within it are seeds. A fruit may contain one or more

seeds; some orchid fruits contain several thousand to a few million seeds! Fruits provide protection for the enclosed seeds and sometimes aid in their dispersal.

There are several types of fruits; their differences result from variations in the structure or arrangement of the flowers from which they were formed. The four basic types of fruits—simple fruits, aggregate fruits, multiple fruits, and accessory fruits—are summarized in **FIGURE 37-10**.

Most fruits are simple fruits. A **simple fruit** develops from a single ovary, which may consist of a single carpel or several fused carpels. At maturity, simple fruits may be fleshy or dry. Two examples of simple, fleshy fruits are berries and drupes. A **berry** is a fleshy fruit that has soft tissues throughout and contains few to many seeds; a blueberry is a berry, as are grapes, cranberries, bananas, and tomatoes. Many so-called berries do not fit the botanical definition. Strawberries, raspberries, and mulberries, for example, are not berries; these three fruits are discussed shortly.

A **drupe** is a simple, fleshy or fibrous fruit that contains a hard stone (pit) surrounding a single seed. Examples of drupes are peaches, plums, olives, and almonds. The almond shell is actually the stone, which remains after the rest of the fruit has been removed.

Many simple fruits are dry at maturity; some of them split open, usually along seams, called **sutures**, to release their seeds. A milkweed pod is an example of a **follicle**, a simple, dry fruit that develops from a single carpel and splits open along one suture to release its seeds. A **legume** is a simple, dry fruit that develops from a single carpel and splits open along two sutures. Pea pods are legumes, as are green beans, although both are generally harvested before the fruit has dried out and split open. Pea seeds are usually removed from the fruit and consumed, whereas in green beans the entire fruit and seeds are eaten. A **capsule** is a simple, dry fruit that develops from two or more fused carpels and splits open along two or more sutures or pores. Iris, poppy, and cotton fruits are capsules.

Other simple, dry fruits, such as **caryopses** (*sing.*, *caryopsis*), or **grains**, do not split open at maturity. Each caryopsis contains a single seed. Because the seed coat is fused to the fruit wall, a caryopsis looks like a seed rather than a fruit. Kernels of corn and wheat are fruits of this type.

An **achene** is similar to a caryopsis in that it is simple and dry, does not split open at maturity, and contains a single seed. However, the seed coat of an achene is not fused to the fruit wall. Instead, the single seed is attached to the fruit wall at one point only, permitting an achene to be separated from its seed. The sunflower fruit is an example of an achene. One can peel off the fruit wall (the shell) to reveal the sunflower seed within.

Nuts are simple, dry fruits that have a stony wall and do not split open at maturity. Unlike achenes, nuts are usually large, single seeded, and often derived from a compound ovary. Examples of nuts are chestnuts, acorns, and hazelnuts. Many so-called nuts do not fit the botanical definition. Peanuts and Brazil nuts, for example, are seeds, not nuts.

Aggregate fruits are a second main type of fruit. An **aggregate fruit** is formed from a single flower that contains several to many separate (free) carpels (**FIG. 37-11**). After fertilization, each ovary from each individual carpel enlarges. As they enlarge, the

Berry (simple fruit)
A simple, fleshy fruit in which the fruit wall is soft throughout.
Tomato (*Lycopersicon lycopersicum*)

Caryopsis (simple fruit)
A simple, dry fruit in which the fruit wall is fused to the seed coat.
Wheat (*Triticum*)

Drupe (simple fruit)
A simple, fleshy fruit in which the inner wall of the fruit is a hard stone.
Peach (*Prunus persica*)

Achene (simple fruit)
A simple, dry fruit in which the fruit wall is separate from the seed coat.
Sunflower (*Helianthus annuus*)

Follicle (simple fruit)
A simple, dry fruit that splits open along one suture to release its seeds; fruit is formed from ovary that consists of a single carpel.
Milkweed (*Asclepias syriaca*)

Nut (simple fruit)
A simple, dry fruit that has a stony wall, is usually large, and does not split open at maturity.
Oak (*Quercus*)

Aggregate fruit
A fruit that develops from a single flower with several to many pistils (i.e., carpels are not fused into a single pistil).
Blackberry (*Rubus*)

Legume (simple fruit)
A simple, dry fruit that splits open along two sutures to release its seeds; fruit is formed from ovary that consists of a single carpel.
Green bean (*Phaseolus vulgaris*)

Multiple fruit
A fruit that develops from the ovaries of a group of flowers.
Mulberry (*Morus*)

Capsule (simple fruit)
A simple, dry fruit that splits open along two or more sutures or pores to release its seeds; fruit is formed from ovary that consists of two or more carpels.
Iris (*Iris*)

Accessory fruit
A fruit composed primarily of nonovarian tissue (such as the receptacle or floral tube).
Apple (*Malus sylvestris*)

Figure 37-10 Fruit types

Fruits are botanically classified into four groups—simple, aggregate, multiple, and accessory—based on their structure and mechanism of seed dispersal.

Figure 37-11 An aggregate fruit

(a) Cutaway view of a blackberry flower (*Rubus*), showing the many separate carpels in the center of the flower. **(b)** A developing blackberry fruit is an aggregate of tiny drupes. The little “hairs” on the blackberry are remnants of stigmas and styles. **(c)** Developing blackberry fruits at various stages of maturity.

ovaries may fuse to form a single fruit. Raspberries, blackberries, and magnolia fruits are examples of aggregate fruits.

A third type is the **multiple fruit**, formed from the ovaries of many flowers that grow in proximity on a common floral stalk. The ovary from each flower fuses with nearby ovaries as it develops and enlarges after fertilization. Pineapples, figs, and mulberries are multiple fruits.

Accessory fruits are the fourth type. They differ from other fruits in that plant tissues in addition to ovary tissue make up the fruit. For example, the edible portion of a strawberry is the red, fleshy receptacle. Apples and pears are also

accessory fruits; the outer part of each of these fruits is an enlarged *floral tube*, consisting of receptacle tissue along with portions of the calyx, that surrounds the ovary (**FIG. 37-12**).

Seed dispersal is highly varied

Wind, animals, water, and explosive dehiscence disperse the various seeds and fruits of flowering plants (**FIG. 37-13**). Effective methods of seed dispersal have made it possible for certain plants to expand their geographic range. In some cases, the seed is the actual agent of dispersal; in others, the fruit performs this role. In

Figure 37-12 An accessory fruit

(d) Fleshy fruits such as blackberries (*Rubus*) are eaten by animals such as this white-footed mouse. The seeds are frequently swallowed whole and pass unharmed through the animal's digestive tract.

(e) (Left) An intact fruit of bitter cress (*Cardamine pratensis*), before it has opened. (Right) The fruit splits open with explosive force, flinging the seeds some distance from the plant.

Figure 37-13 Seed (and fruit) dispersal

tumbleweeds, such as Russian thistle, the entire plant is the agent of dispersal because it detaches and blows across the ground, scattering seeds as it bumps along. Tumbleweeds are lightweight and are sometimes blown many kilometers by the wind.

Wind is responsible for seed dispersal in many plants. Plants such as maple trees have winged fruits adapted for wind dispersal. Light, feathery plumes enable other seeds or fruits to be transported by wind, often for considerable distances. Both dandelion fruits and milkweed seeds have this type of adaptation.

Some plants have special structures that aid in dispersal of their seeds and fruits by animals. The spines and barbs of burdock burs and similar fruits catch in animal fur and fall off as the animal moves about.

Fleshy, edible fruits are also adapted for animal dispersal. Birds, bats, primates, grazing ruminants, and ants are common dispersal agents. These animals are attracted to the fruit by its color, location, odor, and taste. As the animal eats these fruits, it either discards or swallows the seeds. Many seeds that are

swallowed have thick seed coats and are not digested; instead, they pass through the digestive tract and are deposited in the animal's feces some distance from the parent plant. In fact, some seeds do not germinate unless they have passed through an animal's digestive tract; the animal's digestive juices probably aid germination by helping break down the seed coat. Some edible fruits apparently contain chemicals that function as laxatives to speed seeds through an animal's digestive tract; the less time these seeds spend in the gut, the more likely they will germinate.

Animals such as squirrels and many bird species also help disperse acorns and other fruits and seeds by burying them for winter use. Many buried seeds are never used by the animal and germinate the following spring. Ants collect the seeds of many plants and take them underground to their nests. Ants disperse and bury seeds for hundreds of plant species in almost every terrestrial environment, from northern coniferous forests to tropical rain forests to deserts.

Both ants and flowering plants benefit from their association. The ants ensure the reproductive success of the plants whose seeds they bury, and the plants supply food to the ants. A seed that is collected and taken underground by ants often contains a special structure called an *elaiosome*, or *oil body*, that protrudes from the seed. Elaiosomes are a nutritious food for ants, which carry seeds underground before removing the elaiosome. Once an elaiosome is removed from a seed, the ants discard the undamaged seed in an underground refuse pile, which happens to be rich in organic material (such as ant droppings and dead ants) and minerals (inorganic nutrients) required by young seedlings. Thus, ants not only bury the seeds away from animals that might eat them but also place the seeds in rich soil that is ideal for germination and seedling growth.

The coconut is an example of a fruit adapted for dispersal by water. The coconut has air spaces that make it buoyant and capable of being carried by ocean currents for thousands of kilometers. When it washes ashore, the seed may germinate and grow into a coconut palm tree.

Some seeds are not dispersed by wind, animals, or water. Such seeds are found in fruits that use *explosive dehiscence*, in which the fruit bursts open suddenly and quite often violently, forcibly discharging its seeds. These fruits burst open due to pressure caused by differences in *turgor* (hydrostatic pressure) as the cells in the fruit dry out. The fruits of plants such as touch-me-not and bitter cress split open so explosively that seeds are scattered a meter or more.

CHECKPOINT 37.3

- What is the difference between pollination and fertilization? Which process occurs first?
- What are the main stages of eudicot embryonic development?
- What is a fruit?
- How are the following fruits distinguished: simple, aggregate, multiple, and accessory?
- What are some characteristics of animal-dispersed seeds and fruits?

37.4 Germination and Early Growth

LEARNING OBJECTIVE

- 9 Summarize the influence of internal and environmental factors on the germination of seeds.

In flowering plants, pollination and fertilization are followed by seed and fruit development. Each seed develops from an ovule and contains an embryonic plant and food to provide nourishment for the embryo during germination. **Germination**—the process of a seed sprouting—and the growth of young seedlings into mature plants are aspects of growth and development. Within a given species, the precise requirements for seed germination represent evolutionary adaptations that protect the young seedlings from adverse environmental conditions. Environmental cues, such as the presence of water and oxygen, proper temperature, and sometimes the presence of light penetrating the soil surface, influence whether or not a seed germinates.

No seed germinates unless it has absorbed water. The embryo in a mature seed is dehydrated, and a watery environment is necessary for active metabolism. When a seed germinates, its metabolic machinery is turned on, and numerous materials are synthesized and others degraded. Therefore, water is an absolute requirement for germination. The absorption of water by a dry seed is **imbibition**. As a seed imbibes water, it often swells to several times its original, dry size (**FIG. 37-14**). Cells imbibe water by adhesion of water onto and into materials such as cellulose, pectin, and starches within the seed.

Germination and subsequent growth require a great deal of energy. Because young plants obtain this energy by converting the energy of food molecules stored in the seed's endosperm or cotyledons to ATP during aerobic respiration, much oxygen is usually needed during germination. (Some plants, such as rice, grow in flooded soil where oxygen is absent and

Figure 37-14 Imbibition

Pinto bean seeds (*Phaseolus vulgaris*) before imbibition (left) and after (right). Dry seeds imbibe water before they germinate.

carry out *alcohol fermentation* during the early stages of germination and seedling growth.)

Temperature is another environmental factor that affects germination. Each species has an optimal, or ideal, temperature at which the germination percentage is highest. For most plants, the optimal germination temperature is between 25°C and 30°C (77°F and 86°F). Some seeds, such as those of apples, require prolonged exposure to low temperatures before their seeds break dormancy and germinate. Some of the environmental factors needed for germination help ensure the survival of the young plant. The requirement of a prolonged low-temperature period ensures that seeds adapted to temperate climates germinate in the spring rather than the fall.

Some plants, especially those with tiny seeds, such as lettuce, require light for germination. A light requirement ensures that a tiny seed germinates only if it is close to the soil surface. If such a seed were to germinate several centimeters below the soil surface, it might not have enough food reserves to grow to the surface. If this light-dependent seed remains dormant until the soil is disturbed and it is brought to the surface, however, it has a much greater likelihood of survival.

Some seeds do not germinate immediately

A mature seed is often dormant and may not germinate immediately even if growing conditions are ideal. In certain seeds, internal factors, which are under genetic control, prevent germination even when all external conditions are favorable. Many seeds are dormant because certain chemicals are present or absent or because the seed coat restricts germination. For example, the seeds of many desert plants contain high concentrations of *abscisic acid* (discussed in Chapter 38), which inhibits germination under unfavorable conditions. Absciscic acid is washed out only when rainfall is sufficient to support the plant's growth after the seed germinates.

Some seeds, such as certain legumes, have extremely hard, thick seed coats that prevent water and oxygen from entering, thereby inducing dormancy. *Scarification*, the process of scratching or scarring the seed coat (physically with a knife or chemically with an acid) before sowing it, induces germination in these plants. Scarification in nature occurs, for example, when these seeds pass through the digestive tracts of animals or when the seed coats are partially digested by soil bacteria.

Eudicots and monocots exhibit characteristic patterns of early growth

Once conditions are right for germination, the first part of the plant to emerge from the seed is the radicle, or embryonic root. As the root grows and forces its way through the soil, it encounters considerable friction from soil particles. A root cap protects the delicate apical meristem of the root tip.

The shoot (the stem with its leaves and reproductive structures) is next to emerge from the seed. Stem tips are not protected by a structure comparable to a root cap, but plants have ways to protect the delicate stem tip as it grows through the

(a) Common bean, a eudicot.

The hook in the stem protects the delicate stem tip as it grows through the soil. Once the shoot emerges from the soil, the hook straightens.

(b) Corn, a monocot. The coleoptile, a sheath of cells, emerges first from the soil. The shoot and leaves grow through the middle of the coleoptile.

Figure 37-15 Germination and seedling growth

soil to the surface. The stem of a bean seedling (a eudicot), for instance, curves over to form a hook so that the stem tip and cotyledons are actually *pulled* up through the soil (FIG. 37-15a). Corn and other grasses (monocots) have a special sheath of cells called a **coleoptile** that surrounds and protects the young shoot (FIG. 37-15b). First, the coleoptile pushes up through the soil, and then the leaves and stem grow through the tip of the coleoptile.

CHECKPOINT 37.4

- Give three examples of environmental factors that influence seed germination in certain plants. What is an advantage of each of these germination requirements?
- CONNECT** How does early seedling development differ in eudicots and monocots?

37.5 Asexual Reproduction in Flowering Plants

LEARNING OBJECTIVES

- 10 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, bulbs, corms, stolons, plantlets, and suckers.
- 11 Define *apomixis*.

Flowering plants have many kinds of asexual reproduction, several of which involve modified stems: rhizomes, tubers,

bulbs, corms, and stolons. A **rhizome** is a horizontal underground stem that may or may not be fleshy. Fleshiiness indicates that the rhizome is used for storing food materials, such as starch (FIG. 37-16a). Although rhizomes resemble roots, they are actually stems, as indicated by the presence of scalelike leaves, buds, nodes, and internodes. (Roots have none of these features.) Rhizomes frequently branch in different directions. Over time, the old portion of the rhizome dies, and the two branches eventually separate to become distinct plants. Irises, bamboos, ginger, and many grasses are examples of plants that reproduce asexually by forming rhizomes.

Some rhizomes produce greatly thickened ends called **tubers**, which are fleshy underground stems enlarged for food storage. When the attachment between a tuber and its parent plant breaks, often as a result of the death of the parent plant, the tuber grows into a separate plant. Potatoes and elephant's ear (*Caladium*) are examples of plants that produce tubers (FIG. 37-16b). The "eyes" of a potato are axillary buds, evidence that the tuber is an underground stem rather than a storage root such as a sweet potato or carrot.

A **bulb** is a modified underground bud in which fleshy storage leaves are attached to a short stem (FIG. 37-16c). A bulb

(a) **Rhizome.** Irises have horizontal underground stems called rhizomes. New aerial shoots arise from buds that develop on the rhizome.

(b) **Tuber.** Potato plants form rhizomes, which enlarge into tubers (the potatoes) at the ends.

(c) **Bulb.** A bulb is a short underground stem to which overlapping, fleshy leaves are attached; most of the bulb consists of leaves.

(d) **Corm.** A corm is an underground stem that is almost entirely stem tissue surrounded by a few papery scales.

(e) **Stolon.** Strawberries reproduce asexually by forming stolons, or runners. New plants (shoots and roots) are produced at every other node.

Figure 37-16 Modified stems

is globose (round) and covered by paperlike bulb scales, which are modified leaves. It frequently forms axillary buds that develop into small daughter bulbs (bulblets). These new bulbs are initially attached to the parent bulb, but when the parent bulb dies and rots away, each daughter bulb can become established as a separate plant. Lilies, tulips, onions, and daffodils are some plants that form bulbs.

A **corm** is a short, erect underground stem that superficially resembles a bulb (FIG. 37-16d). Unlike the bulb, whose food is stored in underground leaves, the corm's storage organ is a thickened underground stem covered by papery scales (modified leaves). Axillary buds frequently give rise to new corms; the death of the parent corm separates these daughter corms, which then become established as separate plants. Familiar garden plants that produce corms include crocus, gladiolus, and cyclamen.

Stolons, or **runners**, are horizontal aboveground stems that grow along the surface and have long internodes (FIG. 37-16e). Buds develop along the stolon, and each bud gives rise to a new shoot that roots in the ground. When the stolon dies, the daughter plants live separately. The strawberry plant produces stolons.

Some plants form detachable *plantlets* (small plants) in notches along their leaf margins. *Kalanchoe*, whose common name is “mother of thousands,” has meristematic tissue that gives rise to an individual plantlet at each notch in the leaf (FIG. 37-17). When these plantlets reach a certain size, they drop to the ground, root, and grow.

Some plants reproduce asexually by producing **suckers**, aboveground shoots that develop from adventitious buds on roots (FIG. 37-18). Each sucker grows additional roots and becomes an independent plant when the parent plant dies. Examples of plants that form suckers are black locust,

Figure 37-18 Suckers in various stages of development
All the suckers are connected to one another through the root system.

pear, apple, cherry, blackberry, and aspen. A quaking aspen (*Populus tremuloides*) colony in the Wasatch Mountains of Utah contains at least 47,000 tree trunks formed from suckers that can be traced back to a single individual; this massive “organism” occupies almost 43 hectares (106 acres). Some weeds, such as field bindweed, produce many suckers. These plants are difficult to control because pulling the plant out of the soil seldom removes all the roots, which can grow as deep as 3 m (10 ft). In fact, in response to wounding, the roots produce additional suckers, which can be a considerable nuisance to humans.

Figure 37-17 Plantlets

The “mother of thousands” (*Kalanchoe*) produces detachable plantlets along the margins of its leaves. The young plantlets drop off and root in the ground.

Apomixis is the production of seeds without the sexual process

Some flowering plants produce embryos in seeds without meiosis and the fusion of gametes. Seed production by **apomixis** is a form of asexual reproduction in which the offspring are maternal clones. For example, an embryo may develop from a diploid cell in the ovule rather than from a diploid zygote that forms from the union of two haploid gametes. Because there is no fusion of gametes, the embryo is virtually genetically identical to the maternal genotype. However, the advantage of apomixis over other methods of asexual reproduction is that the seeds and fruits produced by apomixis can be dispersed by methods associated with sexual reproduction.

Apomixis, which occurs in various species of more than 40 angiosperm families, is often found in plants that are polyploid with varying degrees of sterility. Apomixis allows these sterile plants to reproduce and therefore survive. Examples of

plants that can reproduce by apomixis are dandelions, citrus trees, mango, blackberries, garlic, and certain grasses.

Plant biologists are actively engaged in identifying the genes involved in asexual reproduction by apomixis. For example, it has been demonstrated that mutation of a single gene in *Arabidopsis* can result in production of diploid female gametes, a first step toward apomixis. If researchers can transfer this or similar genes to crop plants that possess superior traits such as high yield, they may be able to develop apomictic crop plants whose traits do not get lost or diluted during the genetic shuffling of sexual reproduction.

CHECKPOINT 37.5

- How are rhizomes and tubers involved in asexual reproduction?
- **CONNECT** How are corms and bulbs similar? How are they different?
- What is apomixis? How is the ability to reproduce by apomixis advantageous compared with other forms of asexual reproduction?

37.6 A Comparison of Sexual and Asexual Reproduction

LEARNING OBJECTIVE

- 12** State the differences between sexual reproduction and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

Sexual reproduction and asexual reproduction are suited for different environmental circumstances. As you know, sexual reproduction results in offspring that are genetically different from the parents; that is, the parental genotypes are not preserved in the offspring. This genetic diversity of offspring may be selectively advantageous, particularly in an unstable, or changing, environment. (We define *environment* broadly to include all external conditions, both living and nonliving, that affect an organism.) If a plant species that reproduces sexually (and is therefore genetically diverse) is exposed to increasing annual temperatures as a result of climate change, for example, some of the individuals may be more fit than the parents or other offspring. The genetic diversity from sexual reproduction may also let the individuals of a species exploit new environments, thereby expanding their range.

You have seen that asexual reproduction results in offspring that are virtually genetically identical to the parent;

that is, the parental genotype is preserved. Assuming that the parent is well adapted to its environment (i.e., the parent has a favorable combination of alleles), this genetic similarity may be selectively advantageous if the environment remains stable (unchanging) for several generations. None of the offspring of asexual reproduction is more fit than the parent, but neither is any less fit.

Despite the apparent advantages of asexual reproduction, most plant species whose reproduction is primarily asexual occasionally reproduce sexually. Even in what appears to be a stable environment, plants are exposed to changing selective pressures, such as changes in the number and kinds of herbivores and parasites, the availability of food, competition from other species, and climate. Sexual reproduction permits species whose reproduction is primarily asexual to increase their genetic variability so that at least some individuals are adapted to the changing selective pressures in a stable environment.

Sexual reproduction has some disadvantages

Although the genetic diversity produced by sexual reproduction is advantageous to a species' long-term survival, sexual reproduction is a costly form of reproduction. Sexual reproduction requires both male and female gametes, which must meet for reproduction to occur. The many adaptations of flowers for different modes of pollination represent one cost of sexual reproduction.

Sexual reproduction produces some individuals with genotypes that are well-adapted to the environment, but it also produces some individuals that are less well-adapted. Therefore, sexual reproduction is usually accompanied by high death rates among offspring, particularly when selective pressures are strong. (As discussed in Chapter 18, however, this aspect of sexual reproduction is an important part of evolution by natural selection.)

Every biological process involves trade-offs, and sexual reproduction is no exception. Although sexual reproduction has its costs, it also has adaptive advantages over asexual reproduction.

CHECKPOINT 37.6

- How does sexual reproduction in plants differ from asexual reproduction?
- **CONNECT** What is an adaptive advantage of sexual reproduction? Why is sexual reproduction considered costly?

Summary: Focus on Learning Objectives

37.1 The Flowering Plant Life Cycle (page 783)

1 Describe the functions of each part of a flower.

- **Sepals** cover and protect the flower parts when the flower is a bud. **Petals** play an important role in attracting animal pollinators to the flower.
- **Stamens** produce pollen grains. Each stamen consists of a thin stalk (the **filament**) attached to a saclike structure (the **anther**).
- The **carpel** is the female reproductive unit. A **pistil** may consist of a single carpel or a group of fused carpels. Each pistil has three sections: a **stigma**, on which the pollen grains land; a **style**, through which the pollen tube grows; and an **ovary** that contains one or more **ovules**.

2 Identify where eggs and pollen grains are formed within the flower.

- **Pollen grains** form within pollen sacs in the anther.
- An egg and two **polar nuclei**, along with several other nuclei, are formed in the ovule. Both egg and polar nuclei participate directly in fertilization.

37.2 Pollination (page 786)

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, and bats).

- Flowers pollinated by insects are often yellow or blue and have a scent. Bird-pollinated flowers are often yellow, orange, or red and do not have a strong scent. Bat-pollinated flowers often have white petals and are scented.

4 Define *coevolution* and give examples of ways that plants and their animal pollinators have affected each other's evolution.

- **Coevolution** is reciprocal adaptation caused by two different species (such as flowering plants and their animal pollinators) forming an interdependent relationship and affecting the course of each other's evolution. For example, flowers with large, showy petals and scent have evolved in some plants, whereas hairy bodies that catch and hold sticky pollen grains have evolved in bees.

37.3 Fertilization and Seed and Fruit Development (page 789)

5 Distinguish between pollination and fertilization.

- **Pollination** is the transfer of pollen grains from anther to stigma. After pollination, **fertilization**, the fusion of gametes, occurs.
- Flowering plants undergo **double fertilization**. The egg fuses with one sperm cell, forming a zygote (fertilized egg) that eventually develops into a multicellular embryo in the **seed**. The two polar nuclei fuse with the second sperm cell, forming a triploid nutritive tissue called **endosperm**.

6 Trace the stages of embryo development in flowering plants and list and define the main parts of seeds.

- A eudicot embryo develops in the seed in an orderly fashion, from proembryo to globular embryo to the heart stage to the torpedo stage.
- A mature seed contains both a young plant embryo and nutritive tissue—stored in the endosperm or in the **cotyledons** (seed leaves)—for use during germination. A tough, protective **seed coat** surrounds the seed.

7 Explain the relationships among ovules, ovaries, seeds, and fruits.

- Ovules are structures with the potential to develop into seeds, whereas ovaries are structures with the potential to develop into fruits. Seeds are enclosed within **fruits**, which are mature, ripened ovaries.

8 Distinguish among simple, aggregate, multiple, and accessory fruits.

- **Simple fruits** develop from a single ovary that consists of one carpel or several fused carpels. **Aggregate fruits** develop from a single flower with many separate ovaries. **Multiple fruits** develop from the ovaries of many flowers growing in close proximity on a common axis. In **accessory fruits**, the major part of the fruit consists of tissue other than ovary tissue.

37.4 Germination and Early Growth (page 796)

9 Summarize the influence of internal and environmental factors on the germination of seeds.

- **Germination** is the process of seed sprouting. Internal factors affecting whether a seed germinates include the maturity of the embryo; the presence or absence of chemical inhibitors; and the presence or absence of hard, thick seed coats.
- External environmental factors that may affect germination include requirements for oxygen, water, temperature, and light.

37.5 Asexual Reproduction in Flowering Plants (page 797)

10 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, bulbs, corms, stolons, plantlets, and suckers.

- A **rhizome** is a horizontal underground stem. A **tuber** is a fleshy underground stem enlarged for food storage. A **bulb** is a modified underground bud with fleshy storage leaves attached to a short stem. A **corm** is a short, erect underground stem covered by papery scales. A **stolon** is a horizontal aboveground stem with long internodes.
- Some leaves have meristematic tissue along their margins and give rise to detachable **plantlets**.
- Roots may develop adventitious buds that develop into **suckers**. Suckers produce additional roots and may give rise to new plants.

11 Define *apomixis*.

- **Apomixis** is the production of seeds and fruits without sexual reproduction.

37.6 A Comparison of Sexual and Asexual Reproduction (page 800)

12 State the differences between sexual reproduction and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

- Sexual reproduction involves the union of two gametes; the offspring produced by sexual reproduction are genetically variable. Asexual reproduction involves the formation of offspring without the fusion of gametes; the offspring are virtually genetically identical to the single parent.

- Genetic diversity among offspring produced by sexual reproduction may let certain individuals survive in a changing environment or exploit new environments. Sexual reproduction is costly because both male and female gametes must be produced and must meet.
- Genetic similarity among offspring produced by asexual reproduction may be advantageous if the environment is stable. Most plant species whose reproduction is primarily asexual occasionally reproduce sexually, thereby increasing their genetic variability.

Test Your Understanding

Know and Comprehend

1. The normal order of whorls from the flower's periphery to the center is (a) sepals, petals, carpels, stamens (b) stamens, carpels, sepals, petals (c) sepals, petals, stamens, carpels (d) petals, carpels, stamens, sepals (e) carpels, stamens, petals, sepals
2. A pistil consists of (a) stigma, style, and stamen (b) anther and filament (c) sepal and petal (d) stigma, style, and ovary (e) radicle, hypocotyl, and plumule
3. The transfer of pollen grains from anther to stigma is (a) fertilization (b) double fertilization (c) pollination (d) germination (e) apomixis
4. The observation that insects with long mouthparts pollinate long, tubular flowers and insects with short mouthparts pollinate flowers with short corollas is explained by (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) explosive dehiscence
5. The process of _____ in flowering plants involves one sperm cell fusing with an egg cell and one sperm cell fusing with two polar nuclei. (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) pollination
6. The nutritive tissue in the seeds of flowering plants that is formed from the union of a sperm cell and two polar nuclei is called the (a) plumule (b) endosperm (c) cotyledon (d) hypocotyl (e) radicle
7. After fertilization, the ovule develops into a _____, and the ovary develops into a _____. (a) fruit; seed (b) seed; fruit (c) calyx; corolla (d) corolla; calyx (e) follicle; legume
8. In plants that lack endosperm in their mature seeds, the cotyledons function to (a) enclose and protect the seed (b) aid in seed dispersal (c) serve as an absorptive embryonic root (d) store food reserves (e) attach the embryo within the ovule
9. _____ fruits develop from many ovaries of a single flower, whereas _____ fruits develop from the ovaries of many separate flowers. (a) multiple; accessory (b) simple; accessory (c) aggregate; multiple (d) accessory; aggregate (e) simple; multiple

10. A horizontal underground stem that may or may not be fleshy and that is often specialized for asexual reproduction is called a (a) stolon (b) bulb (c) corm (d) rhizome (e) tuber

Apply and Analyze

11. Place the following events in the correct order: 1. pollen tube grows into ovule 2. insect lands on flower to drink nectar 3. embryo develops within the seed 4. fertilization occurs 5. pollen carried by insect contacts stigma (a) 2, 5, 1, 4, 3 (b) 1, 4, 2, 5, 3 (c) 3, 2, 5, 1, 4 (d) 5, 1, 3, 4, 2 (e) 2, 5, 4, 3, 1
12. **VISUALIZE** Draw a simple sketch of a eudicot flower with a single pistil and label a petal, anther, ovule, stigma, ovary, filament, stamen, style, and sepal.
13. **VISUALIZE** Sketch the kinds of flowers that form simple, aggregate, multiple, and accessory fruits.

Evaluate and Synthesize

14. Using what you have learned in this chapter, speculate whether it is more likely that offspring of asexual reproduction develop in close proximity to or widely dispersed from the parent plant. Explain your reasoning. How could you test your hypothesis?
15. Which type of reproduction, sexual or asexual, might be more beneficial in the following circumstances and why? (a) a perennial (plant that lives more than two years) in a stable environment (b) an annual (plant that lives one year) in a rapidly changing environment (c) a plant adapted to an extremely narrow climate range
16. **EVOLUTION LINK** Is seed dispersal by ants an example of coevolution? Why or why not?
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** What is the value to society of research on genes that control flowering? on those that control seed germination?

38 Plant Developmental Responses to External and Internal Signals

The ultimate control of plant growth and development, which includes all the changes that take place during the entire life of an individual, is genetic. If the genes required for development of a particular trait, such as the shape of a leaf, the color of a flower, or the type of root system, are not present, that characteristic does not develop. When a particular gene is present, its expression—that is, how it exhibits itself as an observable feature of an organism—is determined by several factors, including regulatory signals from other genes and from the environment. The location of a cell in the young plant body also has a profound effect on gene expression during development. Chemical signals from adjacent cells help a cell “perceive” its location within the plant body. Each cell’s spatial environment helps determine what that cell ultimately becomes.

Growth and development, including a plant’s responses to various changes in its environment, are controlled by plant *hormones*, organic molecules that are present in very low concentrations in plant tissues and that act as chemical signals between cells. Environmental cues, such as changing day length and variations in precipitation and temperature, exert an important influence on gene expression and hormone production, as they do on all aspects of plant growth and development.

For example, the initiation of sexual reproduction is often under environmental control, particularly in temperate latitudes, and plants switch from vegetative to reproductive growth after receiving appropriate signals from the environment. Many flowering plants are sensitive to changes in the relative amounts of daylight and darkness that accompany the changing seasons,

KEY CONCEPTS

- 38.1** A plant may respond to an external stimulus, such as light, gravity, or touch, by a tropism, a directional growth response. Study of tropisms has helped biologists elucidate links between the external environment and internal signals such as hormones.
- 38.2** Hormones are chemical signals responsible for coordinating and regulating many aspects of plant development. Although there are many plant hormones, six have been well characterized: auxins, gibberellins, cytokinins, ethylene, abscisic acid, and brassinosteroids.
- 38.3** Plants have different receptors that detect various colors of light. Phytochrome detects red light and far-red light, which affect several aspects of development, including the timing of flowering.
- 38.4** The exposure of a plant to a pathogen or herbivore causes a localized hypersensitive response that seals off the affected area. The plant also sends signals from the site of localized infection, leading to systemic acquired resistance and long-lasting, enhanced defenses throughout the plant.

PHOTO: Black-eyed Susan. This plant (*Rudbeckia hirta*) produces flowers in response to the shortening nights of spring and early summer. mikedray/Shutterstock.com

and these plants flower in response to those changes (see photograph). In this chapter we will see that plants use light as an external signal to help regulate many aspects of growth and development, such as tropisms (directional growth), time of flowering, shade avoidance, and circadian rhythms.

Other plants have temperature requirements that induce sexual reproduction. Thus, plants continually perceive information from the environment and use this information to help regulate normal growth and development. We consider these various aspects of growth and development in this chapter.

38.1 Tropisms

LEARNING OBJECTIVE

- 1 Describe phototropism, gravitropism, and thigmotropism.

Plants exhibit movements in response to environmental stimuli such as light, gravity, and touch. A plant may respond to such an external stimulus by directional growth; that is, the direction of growth depends on the direction of the stimulus. Such a directional growth response, called a **tropism**, results in a change in the position of a plant part. Tropisms are irreversible and may be positive or negative, depending on whether the plant grows toward the stimulus (a positive tropism) or away from it (a negative tropism). Tropisms are under hormonal control, which is discussed later in the chapter.

Phototropism is the directional growth of a plant caused by light (FIG. 38-1). Most growing shoot tips exhibit positive phototropism by bending (growing) toward light, something you may have observed if you place houseplants near a sunny window. This growth response increases the likelihood that stems and leaves receive adequate light for photosynthesis. The bending response of phototropism is triggered by blue light with wavelengths less than 500 nm. (You may recall from Chapter 34 that blue light also induces stomata to open.)

For a plant or any organism to have a biological response to light, it must contain a light-sensitive substance, called a *photoreceptor*, to absorb the light. The photoreceptor that

Figure 38-1 Phototropism

A bean seedling (*Phaseolus vulgaris*) grows in the direction of light and therefore exhibits positive phototropism. The bending is caused by greater elongation on the shaded side of the stem than on the lighted side.

absorbs blue light and triggers the phototropic response and other blue-light responses (such as stomatal opening) is a family of yellow pigments called **phototropins**. Phototropins are light-activated **kinases**, enzymes that transfer phosphate groups. There is evidence that phototropins become phosphorylated—that is, a phosphate group is added—in response to blue light. Thus, phosphorylation is an early step in the blue-light-signaling pathway.

Growth in response to the direction of gravity is called **gravitropism**. Most stem tips exhibit negative gravitropism by growing away from Earth's center, whereas most root tips exhibit positive gravitropism (FIG. 38-2). The root cap is the site of gravity perception in roots; when the root cap is removed, the root continues to grow, but it loses any ability to perceive gravity. Special cells in the root cap possess starch-containing **amyloplasts** (see Fig. 3-9a) that collect toward the bottom of the cells in response to gravity, and these amyloplasts may initiate at least some of the gravitropic response. If the root

Figure 38-2 Gravitropism

A corn (*Zea mays*) seedling was turned on its side three days after germinating. In 1 hour the root and shoot tips had curved.

is put in a different position, as when a potted plant is laid on its side, the amyloplasts tumble to a new position, always settling in the direction of gravity. The gravitropic response (bending) occurs shortly thereafter and involves the hormone *auxin* (discussed later in the chapter).

Despite the movement of amyloplasts in response to gravity, researchers question their role in gravitropism. A mutant *Arabidopsis thaliana* plant that lacks amyloplasts in its root cap cells still responds gravitropically when placed on its side, indicating that roots do not necessarily need amyloplasts to respond to gravity. Ongoing research may clarify how roots perceive gravity.

Thigmotropism is growth in response to a mechanical stimulus, such as contact with a solid object. The twining or curling growth of tendrils or stems, which helps attach a climbing plant such as a vine to some type of support, is an example of thigmotropism (see Fig. 34-14b).

CHECKPOINT 38.1

- **CONNECT** How does the yellow color of phototropins relate to the wavelengths of light to which they respond?
- How do phototropism, gravitropism, and thigmotropism differ?

38.2 Plant Hormones and Development

LEARNING OBJECTIVES

- 2 Describe a general mechanism of action for plant hormones, using auxin as your example.
- 3 Describe early auxin experiments involving phototropism.
- 4 List several ways that each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, abscisic acid, and brassinosteroids.

A plant **hormone** is an organic compound that acts as a chemical signal eliciting a variety of responses that regulate growth and development. The study of plant hormones is challenging because hormones are effective in extremely small concentrations (less than 10^{-6} mol/L). In addition, the effects of different plant hormones overlap, and it is difficult to determine which hormone, if any, is the primary cause of a particular response. Plant hormones may also stimulate a response at one concentration and inhibit that same response at a different concentration.

For many years, biologists studied five major classes of plant hormones: auxins, gibberellins, cytokinins, ethylene, and abscisic acid. More recently, researchers have uncovered compelling evidence for brassinosteroids as a sixth plant hormone. Additional plant hormones will probably be characterized in the future. (TABLE 38-1 summarizes the six plant hormones.)

Plant hormones act by signal transduction

Researchers have used molecular genetic techniques to better understand the biology of plant hormones. *Arabidopsis* mutants are particularly useful. For example, different mutants have defects in hormone synthesis, hormone transport, signal reception, or signal transduction (FIG. 38-3). In **signal transduction** a receptor converts an extracellular signal into an intracellular signal that causes one or more cellular responses.

Such mutants enable plant biologists to identify and clone genes involved in these aspects of hormone biology. Studying the mutant phenotypes helps plant biologists establish connections between the mutant genes and specific physiological activities involved in growth and development. Using this research, biologists are elucidating the general mechanisms of plant hormone action, an important goal of systems biology.

As discussed in Chapter 6, it appears that many plant hormones bind to *enzyme-linked receptors*; the hormone binds to the receptor, where it triggers an enzymatic reaction of some sort. Let us consider a specific example that involves the plant

Table 38-1 Plant Hormones

Hormone	Site of Production	Principal Actions
Auxins (e.g., IAA)	Shoot apical meristem, young leaves, seeds	Stem elongation, apical dominance, root initiation, fruit development
Gibberellins	Young leaves and shoot apical meristems, embryo in seed	Seed germination, stem elongation, flowering, fruit development
Cytokinins (e.g., zeatin)	Various sites in plants	Cell division, delay of leaf senescence, inhibition of apical dominance, flower development, embryo development, seed germination
Ethylene	Stem nodes, ripening fruit, damaged or senescing tissue	Fruit ripening, responses to environmental stressors, seed germination, maintenance of apical hook on seedlings, root initiation, senescence and abscission in leaves and flowers
Abscisic acid	Almost all cells that contain plastids (leaves, stems, roots)	Seed dormancy, responses to water stress
Brassinosteroids (e.g., brassinolide)	Shoots (leaves and flower buds), seeds, fruits	Light-mediated gene expression, cell division, cell elongation, seed germination, vascular development

Figure 38-3 General mechanism of action for the hormone auxin

Various external and/or internal signals trigger the synthesis of auxin. Once synthesized, auxin is transported directionally, causing local auxin gradients to form in the plant. In turn, these gradients trigger specific developmental responses in certain cells by reception, signal transduction, and response (discussed shortly). *Arabidopsis* mutants have been identified with defects involving auxin synthesis, auxin transport, or other steps in the process.

hormone *auxin*, which is known to cause rapid changes in gene expression. One receptor for auxin is located in either the cytosol or the nucleus and has a three-dimensional shape that binds to the auxin molecule. The binding of auxin to its receptor (designated the *TIR1* receptor) catalyzes the attachment of the molecule *ubiquitin* to repressor proteins that inhibit the transcription of certain genes, designated *auxin response genes* (FIG. 38-4).

The ubiquitinated protein is therefore targeted for degradation into peptide fragments in a proteasome. (See

Figure 14-17, which shows the ubiquitin–proteasome degradation of proteins.) As a result, transcription of the auxin response gene occurs, resulting in changes in cell growth and development.

The *TIR1* receptor for auxin is an *F-box protein*. The F-box is a short sequence of amino acids found in molecules that catalyze the addition of ubiquitin tags to proteins targeted for destruction. Interestingly, all animals, plants, and fungi examined to date use ubiquitin to target proteins for destruction, but bacteria do not, which suggests that the use of ubiquitin tags evolved early in

Figure 38-4 Model of a signal transduction pathway for auxin

What part of the grass coleoptile depends on light for phototropic growth?

HYPOTHESIS: The coleoptile tip is required for the growth (bending) of the coleoptile shaft that accompanies exposure to light coming from one direction.

EXPERIMENT: Some canary grass coleoptiles were uncovered, some were covered only at the tip, some had the tip removed, and some were covered everywhere but at the tip (*left*). The covers were impervious to light.

RESULTS AND CONCLUSION: After exposure to light coming from one direction, the uncovered plants and the plants with uncovered tips grew toward the light (*right*). The plants with tips covered or removed did not bend toward light. The Darwins concluded that some substance was produced in the tip and transmitted to the lower part, causing it to bend.

SOURCES: C.R. Darwin, *The Power of Movement in Plants* (John Murray, London, 1880); P. Boysen-Jensen, "Concerning the Performance of Phototropic Stimuli on the *Avena* Coleoptile," *Berichte der Deutschen Botanischen Gesellschaft* (Reports of the German Botanical Society), Vol. 31 (1913): 559–566.

Figure 38-5 The Darwins' phototropism experiments

PREDICT Devise an experiment to test the hypothesis that a minimum period of light exposure is required to produce bending.

eukaryote evolution and was conserved as the various groups of eukaryotes diversified. Plants have more than 700 different F-box proteins. Although not much is known about most of them, it is significant that researchers have identified other plant hormones and signaling molecules that use F-box proteins as receptors, including gibberellin, ethylene, and abscisic acid.

Auxins promote cell elongation

Charles Darwin, the British naturalist best known for developing the scientific theory of natural selection to explain evolution, also provided the first evidence for the existence of auxins. The experiments that Darwin and his son Francis performed in the 1870s involved positive phototropism, the directional growth of plants toward light. The plants they used were newly germinated canary grass seedlings. As in all grasses, the first part of a canary grass seedling to emerge from the soil is the coleoptile, a protective sheath that encircles the stem. When coleoptiles are exposed to light from only one direction, they bend toward the light. The bending occurs below the tip of the coleoptile.

The Darwins tried to influence this bending in several ways (**FIG. 38-5**). For example, they covered the tip of the coleoptile as soon as it emerged from the soil. When they covered that part of the coleoptile above where the bend would be expected to occur, the plants did not bend. On other plants, they removed the

coleoptile tip and found that bending did not occur. When the bottom of the coleoptile where the curvature would occur was shielded from the light, the coleoptile bent toward light. From these experiments, the Darwins concluded that "some influence is transmitted from the upper to the lower part, causing it to bend."

In the 1920s, Frits Went, a young Dutch scientist, isolated the phototropic hormone from oat coleoptiles. He removed the coleoptile tips and placed them on tiny blocks of agar for a period of time. When he put one of these agar blocks squarely on a decapitated coleoptile, normal growth resumed. When he placed one of these agar blocks to one side of the tip of a decapitated coleoptile in the dark, bending occurred (**FIG. 38-6**). The results indicated that the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile. Went named this substance **auxin** (from the Greek *aux*, "enlarge" or "increase").

Auxin is a group of several natural (and artificial) plant hormones; the most common and physiologically important auxin is **indoleacetic acid (IAA)**. The purification and elucidation of the primary auxin's chemical structure were accomplished in the mid-1930s by a research team led by Kenneth Thimann at the California Institute of Technology.

The movement of auxin in the plant is said to be *polar*, or unidirectional. Auxin moves downward along the shoot–root axis from its site of production, usually the shoot apical

Key Experiment

Is there a chemical substance responsible for elongation of coleoptiles, and can it be isolated?

HYPOTHESIS: The factor responsible for coleoptile growth is a diffusible chemical that can be isolated from coleoptile tips.

EXPERIMENT: Coleoptile tips were placed on agar blocks for a period of time (a). The agar block was transferred to a decapitated coleoptile. It was placed off-center, and the coleoptile was left in darkness (b).

RESULTS AND CONCLUSION: The coleoptile bent (c), indicating that a chemical moved from the original coleoptile tip to the agar block and from there to the same side of the decapitated coleoptile, causing that side to elongate.

SOURCE: F. Went, "A Growth Substance and Growth," *Recueils Travaux Botaniques Néerlandais* (Collections of Dutch Botanical Works), Vol. 25 (1928: 1–116).

Figure 38-6 Isolating auxin from coleoptiles

PREDICT Devise an experiment to test the hypothesis that the auxin that has diffused into the agar blocks is sensitive to heat.

meristem. (Young leaves and seeds are also sites of auxin production.) This directional cell-to-cell transport results in an *auxin gradient* (a spatial difference in auxin concentration) that triggers specific responses. Special auxin transport proteins in the plasma membranes of plant cells control the movement of auxin out of cells; this process is responsible for the directional movement of auxin. Mutations in auxin transport proteins inhibit the transmission of auxin, which normally moves about 1 cm per hour.

Auxin's most characteristic action is promotion of cell elongation in stems and coleoptiles. This effect, apparently exerted by acidification of cell walls, increases their plasticity and thus enables them to expand under the force of the cell's internal turgor pressure. Auxin's effect on cell elongation also provides an explanation for phototropism. When a plant is exposed to a light from only one direction, some of the auxin

migrates laterally to the shaded side of the stem before moving down the stem by polar transport. Because of the greater auxin concentration on the shaded side of the stem, the cells there elongate more than the cells on the light side, and the stem bends toward the light (FIG. 38-7). Auxin is also involved in gravitropism and thigmotropism.

Auxin exerts other effects on plants. For example, some plants tend to branch out very little when they grow. Growth in these plants occurs almost exclusively from the apical meristem rather than from axillary buds, which do not develop as long as the terminal bud is present. Such plants are said to exhibit **apical dominance**, the inhibition of axillary bud growth by the apical meristem. In plants with strong apical dominance, auxin produced in the apical meristem inhibits axillary buds near the apical meristem from developing into actively growing shoots. When the apical meristem is pinched off, the auxin source is removed, and axillary buds grow to form branches. Apical dominance is often quickly reestablished, however, as one branch begins to inhibit the growth of others. Other hormones (ethylene and cytokinin, both discussed later) are also involved in apical dominance. As with many physiological activities, the changing ratios of these hormones may be the factor responsible for apical dominance.

Auxin produced by developing seeds stimulates the development of the fruit. When auxin is applied to certain flowers

Figure 38-7 Phototropism and the unequal distribution of auxin

Auxin travels down the side of the stem or coleoptile away from the light, causing cells on the shaded side to elongate. Therefore, the stem or coleoptile bends toward light.

Figure 38-8 Auxin and root development on stem cuttings

Many adventitious roots developed on a honeysuckle (*Lonicera fragrantissima*) cutting placed in a solution with a high concentration of synthetic auxin (left). Fewer roots developed in a lower auxin concentration (middle). The cutting placed in water (no auxin) served as a control and did not form roots in the same period (right).

in which fertilization has not occurred (and therefore in which seeds are not developing), the ovary enlarges and develops into a seedless fruit. Seedless tomatoes are produced in this manner.¹ Auxin is not the only hormone involved in fruit development, however.

Some manufactured, or synthetic, auxins have structures similar to that of IAA. The synthetic auxin naphthalene acetic acid stimulates root development on stem cuttings and is used for asexual propagation, particularly of woody plants with horticultural importance (FIG. 38-8). The synthetic auxins 2,4-D and 2,4,5-T have been used as selective herbicides (weed killers). These compounds kill plants with broad leaves but, for reasons not completely understood, do not kill grasses. Both herbicides are similar in structure to IAA and disrupt the plants' normal growth processes. Because many of the world's most important crops are grasses (such as wheat, corn, and rice), 2,4-D and 2,4,5-T can kill broad-leaf weeds that compete with these crops. The use of 2,4,5-T is no longer allowed in the United States, however, because of its association with dioxins, a group of mildly to very toxic compounds formed as byproducts when 2,4,5-T is manufactured.

Gibberellins promote stem elongation

In the 1920s and 1930s, a Japanese biologist was studying a disease of rice in which the young rice seedlings grew extremely tall and spindly, fell over, and died. The cause of the disease was a fungus (*Gibberella fujikuroi*) that produces a chemical substance named **gibberellin (GA)**. Not until after World War II did scientists in Europe and North America learn of the

¹ Not all seedless fruits are produced by treatment with auxin. In Thompson seedless grapes, fertilization occurs but the embryos abort; therefore, the seeds fail to develop. Thompson seedless grapes are sprayed with the hormone gibberellin to increase berry size.

work done by this Japanese scientist and others. During the 1950s and 1960s, studies in the United States and Great Britain showed that gibberellins are produced by healthy plants as well as by the fungus.

Gibberellins are hormones involved in many normal plant functions. The symptoms of the seedling disease are caused by an abnormally high GA concentration in the plant tissue (because both plant and fungus produce gibberellin). Currently, dozens of naturally occurring GAs are known, although only about four function as plant hormones; the rest are inactive precursors. There are no synthetic gibberellins.

Gibberellins promote stem elongation in many plants. When GA is applied to a plant, particularly certain dwarf varieties, this elongation may be spectacular. Some corn and pea plants that are dwarfs as a result of one or more mutations grow to a normal height when treated with GA. Short-stemmed, high-yielding varieties of wheat have short stems because they have a reduced response to GA. These varieties put less of their resources into stem height and more resources into grain production. Gibberellins are also involved in **bolting**, the rapid elongation of a floral stalk that occurs naturally in many plants when they initiate flowering (FIG. 38-9).

Gibberellins cause stem elongation by stimulating cells to divide as well as to elongate. The actual mechanism of cell elongation differs from that caused by auxin, however. Recall that IAA-induced cell elongation involves the acidification of the cell wall. In GA-induced cell elongation, cell wall acidification does not occur; biologists do not yet know how gibberellins modify cell wall properties to cause cell elongation.

Robert Lyons/Visuals Unlimited

Figure 38-9 Gibberellin and stem elongation

Like many biennials, Indian blanket (*Gaillardia pulchella*) grows as a rosette, which is a circular cluster of leaves close to the ground, during its first year (left). It then bolts when it initiates flowering in the second year (right). The plant in bloom grows to 0.6 m (2 ft).

Gibberellins affect several reproductive processes in plants. They stimulate flowering, particularly in long-day plants (discussed later in this chapter). In addition, GAs substitute for the low temperature that biennials require before they begin flowering. If GAs are applied to biennials during their first year of growth, flowering occurs without exposure to a period of low temperature. Gibberellins, like auxin, affect fruit development. Agriculturalists apply GAs to several varieties of grapes to produce larger fruits.

Gibberellins are also involved in seed germination in certain plants. In a classic experiment involving barley seed germination, researchers showed that the release of GA from the embryo triggers the synthesis of α -amylase, an enzyme that digests starch in the endosperm. As a result, glucose becomes available for absorption by the embryo. Although enzymes mobilize starch reserves in many types of seeds, GA control of seed enzymes appears restricted to cereals and other grasses. In addition to mobilizing food reserves in newly germinated grass seeds, application of gibberellins substitutes for low-temperature or light requirements for germination in seeds of plants such as lettuce, oats, and tobacco.

Scientists are actively conducting research in gibberellin signaling and have identified several GA receptors in the nucleus, repressor proteins designated *DELLA proteins*, as well as an F-box protein. When GA is not bound to the receptor, a DELLA protein inhibits transcription of *GA response genes*. When GA is present, it binds to the receptor, which triggers an enzyme that attaches ubiquitin to the DELLA protein. This protein is targeted for degradation into peptide fragments in a proteasome. With the DELLA protein no longer present, transcription of the GA response genes occurs. This signaling process may sound familiar: the GA signal transduction process shares similarities with the auxin signal transduction pathway described earlier in this chapter.

Cytokinins promote cell division

During the 1940s and 1950s, researchers were trying to find substances that might induce plant cells to divide in **tissue culture**, a technique in which cells are isolated from plants and grown in a nutrient medium. (Plant tissue culture is discussed in Chapter 33.) They discovered that cells would not divide without a substance found in coconut milk. Because coconut milk has a complex chemical composition, investigators did not chemically identify the division-inducing substance for some time. Finally, researchers isolated an active substance from a different source, aged DNA from herring sperm. They called it **cytokinin** because it induces cytokinesis, or cytoplasmic division. In 1963, researchers identified the first plant cytokinin, zeatin, in corn. Since then, similar molecules have been identified in other plants. Biologists have also synthesized several cytokinins.

Cytokinins are structurally similar to adenine, a purine base that is part of DNA and RNA molecules. Biologists are beginning to elucidate the cytokinin signal transduction pathway, which is more complex than those of auxin and gibberellin. The cytokinin pathway has multiple steps, each under the control of a number of genes. The presence of feedback loops and links to other signaling pathways adds another level of complexity to the regulation of cytokinin activity.

Cytokinins promote cell division and differentiation of young, relatively unspecialized cells into mature, more specialized cells in intact plants. They are a required ingredient in any plant tissue culture medium and must be present for cells to divide. In tissue culture, cytokinins interact with auxin during the formation of plant organs such as roots and stems (**FIG. 38-10**). For example, in tobacco tissue culture, a high ratio of auxin to cytokinin induces root formation, whereas a low ratio of auxin to cytokinin induces shoot formation.

Cytokinins and auxin also interact in the control of apical dominance. Here their relationship is antagonistic: auxin inhibits the growth of axillary buds, and cytokinin promotes their growth.

One effect of cytokinins on plant cells is to delay the aging process. Plant cells, like all living cells, go through a natural aging process known as **senescence**. Senescence is accelerated in cells of plant parts that are cut, such as flower stems. Botanists think that plants must have a continual supply of cytokinins from the roots. Cut stems, of course, lose their source of cytokinins and therefore age rapidly. When cytokinins are sprayed on leaves of a cut stem of many species, they remain green, whereas unsprayed leaves turn yellow and die.

Despite their involvement in regulating many aspects of plant growth and development, cytokinins currently have few

Figure 38-10 Auxin–cytokinin interactions in tissue culture

Varying amounts of auxin and cytokinin in the culture media produce different growth responses. **(a)** The initial explant is a small piece of sterile tissue from the pith of a tobacco stem, which is placed on nutrient agar. **(b)** Nutrient agar containing 2.0 mg/L of auxin and 0.2 mg/L of cytokinin causes cells to divide and form a clump of undifferentiated tissue called a callus. **(c)** Agar with 2.0 mg/L of auxin and 0.02 mg/L of cytokinin (high ratio of auxin to cytokinin) stimulates root growth. **(d)** Agar with 2.0 mg/L of auxin and 0.5 mg/L of cytokinin (low ratio of auxin to cytokinin) stimulates shoot growth.

commercial applications other than plant tissue culture. However, molecular biologists at the University of Wisconsin have combined a promoter from a gene activated during normal senescence with a gene that encodes an enzyme involved in cytokinin synthesis. (Recall from Chapter 13 that the **promoter** is the nucleotide sequence in DNA to which RNA polymerase attaches to begin transcription.) The leaves of transgenic tobacco plants that contained this recombinant DNA produced more cytokinin and therefore lived longer and continued to photosynthesize (FIG. 38-11). This type of application of molecular technology may have the potential to increase the longevity and productivity of certain crops.

Ethylene promotes abscission and fruit ripening

During the early 20th century, scientists observed that the gas **ethylene** (C_2H_4) has several effects on plant growth, but not until 1934 did they demonstrate that plants produce ethylene. This natural hormone influences many plant processes. Ethylene inhibits

Courtesy of Dr. Richard M. Amasino, University of Wisconsin

Figure 38-11 Cytokinin synthesis and delay of senescence

The tobacco (*Nicotiana tabacum*) plant on the left was genetically engineered to produce additional cytokinin as it aged, whereas the tobacco plant of the same age on the right served as a control. Note the extensive senescence and death of older leaves on the control plant. Depending on the variety, tobacco grows 0.9 to 3 m (3 to 10 ft) tall.

cell elongation, promotes seed germination, promotes apical dominance, and is involved in plant responses to wounding or invasion by disease-causing microorganisms.

Ethylene also has a major role in many aspects of senescence, including fruit ripening. As a fruit ripens, it produces ethylene, which triggers an acceleration of the ripening process and induces the fruit to produce more ethylene, which further accelerates ripening. The expression “one rotten apple spoils the barrel” is true. A rotten apple is one that is overripe and produces large amounts of ethylene, which diffuses and triggers the ripening process in nearby apples. Humans use ethylene commercially to uniformly ripen bananas and tomatoes. These fruits are picked while green and shipped to their destination, where they are exposed to ethylene before they are delivered to grocery stores (FIG. 38-12).

Plants growing in a natural environment encounter rain, hail, wind, and contact with passing animals. All these mechanical stressors alter their growth and development, making them shorter and stockier than plants grown in a greenhouse. Ethylene regulates such developmental responses to mechanical stimuli, known as **thigmomorphogenesis**. Plants that are mechanically disturbed produce additional ethylene, which in turn inhibits stem elongation and enhances cell wall thickening in supporting cells (collenchyma and sclerenchyma). These changes are adaptive because shorter, thicker stems are less likely than longer, thinner stems to be damaged by mechanical stressors.

Ethylene is involved in leaf abscission, which is actually influenced by two antagonistic hormones, ethylene and auxin. As a leaf ages (as autumn approaches, for deciduous trees in temperate climates), the level of auxin in the leaf decreases. Concurrently, cells in the abscission layer at the base of the petiole (where the leaf will break away from the stem) begin producing ethylene.

Researchers studying ethylene signaling have identified a similar mechanism to that already described for auxin and gibberellin. When ethylene is present, it binds to a receptor. This binding triggers an enzyme that attaches ubiquitin to a protein targeted for degradation into peptide fragments in

Illustration Services

Figure 38-12 Ethylene and fruit ripening

Both boxes of tomatoes were picked at the same time, while green. The tomatoes in the box on the right were exposed to an atmosphere containing 100 ppm of ethylene for three days.

a proteasome. At least two F-box proteins are involved in the protein degradation that occurs in ethylene signal transduction.

Abscisic acid promotes seed dormancy

In 1963, two different research teams discovered **abscisic acid (ABA)**. Despite its name, abscisic acid does not induce abscission in most plants. Instead, ABA is involved in a plant's response to stress and in seed **dormancy**, a temporary state of arrested physiological activity. As an environmental stress hormone, ABA particularly promotes changes in plant tissues that are water-stressed. (Recall that ethylene also affects plant responses to certain stressors, such as mechanical stressors and wounding.)

Botanists best understand the effect of abscisic acid on plants suffering from water stress. The level of ABA increases dramatically in the leaves of plants exposed to severe drought conditions. The high level of ABA in the leaves activates a signal transduction process that leads to the closing of stomata. The closing of stomata saves the water that the plant would normally lose by transpiration, thereby increasing the plant's likelihood of survival. As knowledge of ABA signaling in guard cells increases, botanists hope to use this information to engineer crops and horticultural plants that are resistant to drought.

The onset of winter is also a type of stress on plants. A winter adaptation that involves abscisic acid is dormancy in seeds. Many seeds have high levels of ABA in their tissues and do not germinate until the ABA washes out. In a corn mutant unable to synthesize ABA, the seeds germinate as soon as the embryos are mature, even while attached to the ear (FIG. 38-13).

Abscisic acid is not the only hormone involved in seed dormancy. For example, addition of gibberellin reverses the

effects of dormancy. In seeds the level of ABA decreases during the winter, and the level of GA increases. Cytokinins are also implicated in breaking dormancy. Once again, we see that a single physiological activity such as seed dormancy may be controlled in plants by the interaction of several hormones. The plant's actual response may result from changing ratios of hormones rather than the effect of each individual hormone.

Brassinosteroids are plant steroid hormones

Although steroid hormones have long been known to have crucial roles in animals, the roles of steroid hormones in plants were not well characterized until the mid-1990s. The **brassinosteroids (BRs)** are a group of steroids that function as plant hormones. BRs are involved in several aspects of growth and development. *Arabidopsis* mutants that cannot synthesize BRs are dwarf plants with small curly leaves and reduced fertility; researchers can reverse this defect by applying BR to the plant. Studies of these mutants suggest that brassinosteroids are involved in multiple developmental processes, such as cell division, cell elongation, light-induced differentiation, vascular development, and seed germination (FIG. 38-14).

Courtesy of M. G. Neuffer

Figure 38-13 The absence of abscisic acid causes precocious germination

In a corn (*Zea mays*) mutant that does not produce abscisic acid, some of the kernels have germinated while still on the ear, producing roots (arrows).

Figure 38-14 Brassinosteroids and seed germination in *Arabidopsis*

Researchers used a GA-insensitive *Arabidopsis* mutant that produced seeds that did not germinate. (Recall that GA promotes seed germination, so a plant that does not respond to endogenous GA is required.) The scientists overcame the inability of the mutant seeds to germinate by treating them with a brassinosteroid (BR). Note how the percentage of germination increases as the concentration of BR to which the seeds were exposed increases. Adapted from Steber, C.M., and P. McCourt, "A Role for Brassinosteroids in Germination in *Arabidopsis*," *Plant Physiology*, Vol. 125 (2001): 287–297.

Many steps of the BR signaling pathway have been characterized. BRs bind to a receptor kinase in the plant plasma membrane (unlike steroid hormones in animals, which enter the cell and bind to receptors in the cytoplasm or nucleus). When BR binds to its receptor, the receptor phosphorylates molecules in the cytosol, which in turn triggers a signaling cascade that ultimately alters gene expression in the cell. Part of the signal transduction process involves attaching ubiquitin to nuclear proteins targeted for degradation in a proteasome. As a result, the expression of BR target genes is adjusted.

Identification of a universal flower-promoting signal remains elusive

Experiments in which different tobacco species are grafted together indicate that unidentified flower-promoting and flower-inhibiting substances may exist. *Nicotiana silvestris* is a long-day tobacco plant (it requires a short night to flower); a variety of *N. tabacum* is a day-neutral tobacco plant (seasonal changes do not affect when it flowers). When a long-day tobacco is grafted to a day-neutral tobacco and exposed to short nights, both plants flower (FIG. 38-15). The day-neutral tobacco plant flowers sooner than it normally would.

Biologists hypothesize that a flower-promoting substance, *florigen*, may be induced in the long-day plant and transported to the day-neutral plant through the graft union, causing the day-neutral tobacco plant to flower sooner than expected. An intact plant may produce florigen in the leaves and transport it in the phloem to the shoot apical meristem. There, it induces a transition from vegetative to reproductive development, that is, to a meristem that produces flowers.

Figure 38-15 Evidence for the existence of a flower-promoting substance

When a long-day tobacco plant (*Nicotiana silvestris*) is grafted to a day-neutral tobacco plant (*N. tabacum*) and both plants are exposed to a long-day/short-night regimen, they both flower. The day-neutral plant flowers sooner than it normally would, presumably because a flower-promoting substance passes from the long-day plant to the day-neutral one through the graft.

When a botanist grafts a long-day tobacco to a day-neutral tobacco and exposes them to long nights, neither plant flowers. As long as these conditions continue, the day-neutral plants do not flower even when they would normally do so. In this case, the long-day tobacco may produce a flower-inhibiting substance that is transported to the day-neutral tobacco through the graft union. This substance prevents the day-neutral tobacco from flowering.

CHECKPOINT 38.2

- How are signal reception, signal transduction, and altered cell activity part of the general mechanism of action for auxin?
- How is auxin involved in phototropism?
- Which hormones are involved in each of the following physiological processes: (1) seed germination, (2) stem elongation, (3) fruit ripening, (4) leaf abscission, and (5) seed dormancy?

38.3 Light Signals and Plant Development

LEARNING OBJECTIVES

- 5 Explain how varying amounts of light and darkness induce flowering.
- 6 Describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.
- 7 Define *circadian rhythm* and give an example.
- 8 Distinguish between phytochrome and cryptochrome.

Photoperiodism is any response of a plant to the relative lengths of daylight and darkness. Initiation of flowering at the shoot apical meristem is one of several physiological activities that are photoperiodic in many plants. Plants are classified into four main groups—short day, long day, intermediate day, and day neutral—on the basis of how photoperiodism affects their transition from vegetative growth to flowering.

Short-day plants (also called **long-night plants**) flower when the night length is equal to or greater than some critical period (FIG. 38-16a). Thus, short-day plants detect the lengthening nights of late summer or fall. There are two kinds of short-day plants: qualitative and quantitative. In *qualitative short-day plants*, flowering occurs only in short days; in *quantitative short-day plants*, flowering is accelerated by short days. The initiation of flowering in short-day plants is not due to the shorter period of daylight but to the long, uninterrupted period of darkness. The minimum critical night length varies considerably from one plant species to another but falls between 12 and 14 hours for many. Examples of short-day plants are florist's chrysanthemum, cocklebur, and poinsettia, which typically flower in late summer or fall. Poinsettias, for example, typically initiate flower buds in early October in the Northern Hemisphere and flower about 8 to 10 weeks later; hence, they are traditionally associated with Christmas.

Long-day plants (also called **short-night plants**) flower when the night length is equal to or less than some critical period (FIG. 38-16b). In *qualitative long-day plants*, flowering occurs only in long days; in *quantitative long-day plants*, long days accelerate flowering. Long-day plants, such as spinach, black-eyed Susan (see chapter-opening photograph), and the model research plant *Arabidopsis*, flower when they detect the shortening nights of spring and early summer.

Intermediate-day plants do not flower when night length is either too long or too short (FIG. 38-16c). Sugarcane and coleus are intermediate-day plants. These plants flower when exposed to days and nights of intermediate length.

Some plants, called **day-neutral plants**, do not initiate flowering in response to seasonal changes in the period of daylight and darkness but instead respond to some other type

of stimulus, external or internal. Cucumber, sunflower, corn, and onion are examples of day-neutral plants. Many of these plants originated in the tropics, where day length does not vary appreciably during the year. In contrast, short-day, long-day, and intermediate-day plants are temperate or subtropical (midlatitude species).

Plant biologists have experimented with the effects of various light regimens on flowering. FIGURE 38-17 shows how flowering in long-day and short-day plants is affected by different light treatments, including a short-day/long-night regimen with a *night break*, a short burst of light in the middle of the night.

Phytochrome detects day length

The main photoreceptor for photoperiodism and many other light-initiated plant responses (such as germination and seedling establishment) is **phytochrome**, a family of about five blue-green pigment proteins, each of which is coded for by a different gene. A mixture of phytochrome proteins is present in cells of all vascular plants examined so far. For example, five members of the phytochrome family—designated phyA, phyB, phyC, phyD, and phyE—occur in *Arabidopsis*. Phytochrome is also a photoreceptor in certain bacteria, fungi, and slime molds.

(a) **Short-day plants** flower when the night length is equal to or exceeds a certain critical length in a 24-hour period.

(b) **Long-day plants** flower when the night length is equal to or less than a certain critical length in a 24-hour period. The critical length varies among different species; short-day plants may require a shorter night length than long-day plants, as shown.

(c) **Intermediate-day plants** have a narrow night-length requirement.

Figure 38-16 Generalized photoperiodic responses in short-day, long-day, and intermediate-day plants

Figure 38-17 Photoperiodic responses of short-day and long-day plants

A short-day plant flowers when it is grown under long-night conditions (*top middle*), but it does not flower when exposed to a long night interrupted with a brief flash of red light (*top right*). A long-day plant does not flower when grown under long-night conditions (*bottom middle*) unless the long night is interrupted with a brief flash of red light (*bottom right*).

Much of the current knowledge of phytochrome in *Arabidopsis* is based on various mutant plants that do not express a specific phytochrome gene, such as the gene that codes for phyA. By studying the physiological response of plants that do not produce an individual phytochrome, biologists have concluded that the individual forms of phytochrome have both unique and overlapping functions. PhyB appears to exert its influence at all stages of the plant life cycle, whereas the other forms of phytochrome have narrower functions at specific stages in the life cycle.

PhyA and phyB may have antagonistic (opposite) effects on flowering. In long-day plants phyB may inhibit flowering, and phyA may induce flowering. Flowering occurs more rapidly in long-day plants with mutations in the gene that codes for phyB; such mutations reduce or eliminate the production of phyB. In contrast, flowering is delayed or prevented in long-day plants with mutations in the gene that codes for phyA.

Each member of the phytochrome family exists in two forms and readily converts from one form to the other after absorption of light of specific wavelengths. One form, designated **Pr** (for red-absorbing phytochrome), strongly absorbs light with a relatively short red wavelength (660 nm). In the process, the shape of the molecule changes to the second form of phytochrome, **Pfr**, so designated because it absorbs far-red light, which is light with a relatively long red wavelength (730 nm; FIG. 38-18). When it absorbs far-red light, Pfr reverts to the original form, Pr. Pfr is the active form of phytochrome, triggering or inhibiting physiological responses such as flowering.

What does a pigment that absorbs red light and far-red light have to do with daylight and darkness? Sunlight consists of various amounts of the entire spectrum of visible light in addition to ultraviolet and infrared radiation. Sunlight contains more red than far-red light, however, so when a plant is exposed to sunlight, the level of Pfr increases. During the

night, the level of Pfr slowly decreases as Pfr, which is less stable than Pr, is degraded.

The importance of phytochrome to plants cannot be over-emphasized. Timing of day length and darkness is the most reliable way for plants to measure the change from one season to the next. This measurement, which synchronizes the stages of plant development, is crucial for survival, particularly in environments where the climate has an annual pattern of favorable and unfavorable seasons.

Competition for sunlight among shade-avoiding plants involves phytochrome

Plants sense the proximity of nearby plants, which are potential competitors, and react by changing the way they grow and develop. Many plants, from small herbs to large trees, compete for light, a response known as **shade avoidance**, in which plants tend to grow taller when closely surrounded by other plants. If successful, the shade-avoiding plant projects its new growth into direct sunlight and thereby increases its chances of survival.

Since the 1970s, botanists have recognized the environmental factor that triggers shade avoidance: plants perceive changes in the ratio of red to far-red light that result from the presence of nearby plants. The leaves of neighboring plants absorb much more red light than far-red light. (The green pigment chlorophyll strongly absorbs red light during photosynthesis.) In a densely plant-populated area, the ratio of red light to far-red light (r/fr) decreases, affecting the equilibrium between the Pr and Pfr forms, particularly of phyB. This signal triggers a series of responses that cause the shade-avoiding plant, which is adapted to full-light environments,

Figure 38-18 Phytochrome

Each member of the phytochrome family occurs in two forms, designated Pr and Pfr, and readily converts from one form to the other. Red light (660 nm) converts Pr to Pfr, and far-red light (730 nm) converts Pfr to Pr.

to grow taller or flower earlier than it would in a less densely populated area. **FIGURE 38-19** shows an interesting application of additional (reflected) far-red light without the reduction in incoming sunlight that occurs in shade avoidance.

When a plant is using many of its resources for stem elongation, it has fewer resources for new leaves and branches, storage tissues, and reproductive tissues. However, for a shade-avoiding plant that is shaded by its neighbors, a rapid increase in stem length is advantageous because once this plant is taller than its neighbors, it obtains a larger share of unfiltered sunlight.

Phytochrome is involved in other responses to light, including germination

Phytochrome is involved in the light requirement that some seeds have for germination. Seeds with a light requirement must be exposed to light containing red wavelengths. Exposure to red light converts Pr to Pfr, and germination occurs. Many temperate forest species with small seeds require light for germination. (Larger seeds generally do not have a light requirement.) This adaptation enables the seeds to germinate at the optimal time. During early spring, sunlight, including red light, penetrates the bare branches of overlying deciduous trees and reaches the soil between the trees. As spring temperatures

warm, the seeds on the soil absorb red light and germinate. During their early growth, the newly germinated seedlings do not have to compete with the taller trees for sunlight.

Other physiological functions under the influence of phytochrome include sleep movements in leaves (discussed later); shoot dormancy; leaf abscission; and pigment formation in flowers, fruits, and leaves.

Phytochrome acts by signal transduction

Some phytochrome-induced responses are very rapid and short term, whereas others are slower and long term. The rapid responses probably involve reversible changes in the properties of membranes, altering cell ionic balances. Red light, for example, causes potassium ion (K^+) channels to open in cell membranes involved in plant movements caused by changes in turgor. Exposure to far-red light causes the K^+ channels to close. Slower phytochrome-induced responses involve the selective regulation of transcription of numerous genes. For example, phytochrome activates transcription of the gene for the small subunit of *rubisco*, an enzyme involved in photosynthesis (see Chapter 9).

Each phytochrome molecule consists of a protein attached to a light-absorbing photoreceptor. Biologists hypothesize that the absorption of light by the photoreceptor portion of phytochrome elicits a change in the shape of the protein portion of the phytochrome molecule. This change, in turn, triggers one or more **signal transduction** pathways.

One important research tool in studying phytochrome signal transduction is mutant plants that respond as if they were exposed to a particular light stimulus even if they were not. Research indicates that the active form of phytochrome moves from the cytoplasm into the nucleus, where it affects gene expression by activating a **transcription factor**. When activated, the transcription factor, which binds to the promoter of a gene, either turns on or represses transcription that leads to protein synthesis.

In one such pathway, inactive phytochrome (Pr) in the cytoplasm absorbs red light and is converted into the active form, Pfr, which moves into the nucleus. There, phytochrome binds to PIF3 (phytochrome-interacting factor 3), a transcription factor that is already bound to the promoters of light-responsive genes, thereby activating (or repressing) their transcription.

The signal transduction pathway is shut down by far-red light, which is absorbed by the Pfr in the Pfr-PIF3 complex in the nucleus. When Pfr is converted to Pr, it dissociates from PIF3.

The signal transduction pathway just described is not the end of the story. Phytochrome does not regulate just one but numerous light-responsive signaling pathways that affect gene expression. Also, we do not understand the specifics of how the transition from Pr to Pfr participates in so many signaling cascades.

Light influences circadian rhythms

Almost all organisms, including plants, animals, fungi, eukaryotic microorganisms, and many bacteria, appear to have an internal timer, or biological clock, that approximates a 24-hour cycle, the time it takes Earth to rotate around

Cary Wolinsky

Figure 38-19 Colored mulches and plant growth processes

The red mulch reflects far-red light from the ground to the tomato plants. The plants, absorbing the extra far-red light, react as if nearby plants are present. Their aboveground growth is greater, and their fruits ripen earlier. Manipulating mulch colors also modifies yield, flavor, and nutrient content.

Figure 38-20 Sleep movements

its own axis. These internal molecular cycles are known as **circadian rhythms** (from the Latin *circum*, “around,” and *diurn*, “daily”). Circadian rhythms help an organism detect the time of day, whereas photoperiodism enables a plant to detect the time of year.

Why do plants and other organisms exhibit daily circadian rhythms? Predictable environmental changes, such as sunrise and sunset, occur during the course of each 24-hour period. These predictable changes may be important to an individual organism, causing it to change its physiological activities or its behavior (in the case of animals). Researchers think that circadian rhythms help an organism synchronize repeated daily activities so that they occur at the appropriate time each day. If, for example, an insect-pollinated flower does not open at the time of day that pollinating insects are foraging for food, reproduction will be unsuccessful.

Circadian rhythms in plants affect such biological events as gene expression, the timing of photoperiodism (i.e., of seasonal reproduction), the rate of photosynthesis, and the opening and closing of stomata. *Sleep movements* observed in the common bean and other plants are another example of a circadian rhythm (**FIG. 38-20**). During the day, bean leaves are horizontal, possibly for optimal light absorption, but at night the leaves fold down or up, a movement that orients them perpendicular to their daytime position. The biological significance of sleep movements is unknown at this time.

When constant environmental conditions are maintained, circadian rhythms such as sleep movements repeat every 20 to 30 hours, at least for several days. In nature the rising and setting of the sun reset the biological clock so that the cycle repeats every 24 hours. The functioning of the circadian clock is under genetic control.

Mutants of the model plant *Arabidopsis* in which the circadian clock is not synchronized to match the external day-night cycle have been found to contain less chlorophyll, fix less carbon by photosynthesis, grow more slowly, and have less of a competitive advantage than *Arabidopsis* plants with a normal circadian clock.

For *Arabidopsis* and many other plants, two photoreceptors—the red light-absorbing phytochrome and the blue/ultraviolet-A light-absorbing **cryptochrome**—are implicated in resetting the biological clock. Certain amino acid sequences

of the protein portion of phytochrome are homologous with amino acid sequences of clock proteins in fruit flies, fungi, mammals, and bacteria; this molecular evidence strongly supports the circadian-clock role of phytochrome. The evidence for cryptochrome as a clock protein is also convincing. First discovered in plants, cryptochrome counterparts are found in the fruit fly and mouse biological-clock proteins. Possibly both photoreceptors are involved in resetting the biological clock in plants; researchers have evidence that phytochrome and cryptochrome sometimes interact to regulate similar responses.

CHECKPOINT 38.3

- What is phytochrome? What are two roles of phytochrome?
- What are the steps in phytochrome signal transduction?
- In what process is cryptochrome involved?

38.4 Responses to Herbivores and Pathogens

LEARNING OBJECTIVE

- 9 Distinguish between the hypersensitive response and systemic acquired resistance.

Plants lack an immune system such as is found in humans and other mammals, but plants can defend themselves from attack by pathogenic and herbivorous enemies. Each plant cell has an innate immune system to fight against local infections. When a molecule produced by a pathogen or herbivore binds to a receptor in a plant cell, it triggers a signal transduction pathway. As a result, a *hypersensitive response* occurs that seals off the infected area, causing it to die. These *necrotic lesions*, or dead areas, prevent or slow the spread of the initial infection (**FIG. 38-21**).

The plant also sends signals from the site of localized infection, leading to **systemic acquired resistance (SAR)**, a buildup of long-lasting, enhanced resistance throughout the plant. The signal travels in the phloem. Systemic acquired resistance is broad spectrum; that is, SAR is a heightened defense against many types of pathogens, not just the one that caused the initial infection.

Plant biologists continue to discover new hormone-like signaling molecules. Many of these signaling molecules are involved in the defensive responses of plants to disease organisms and insects. Here we briefly consider two groups: jasmonic acid and methyl salicylate.

Nigel Cattlin/Alamy Stock Photo

Figure 38-21 Hypersensitive response

The necrotic lesions on these oak leaves were produced in response to invasion by a fungal pathogen.

Jasmonic acid activates several plant defenses

Jasmonic acid affects several plant processes, such as pollen development, root growth, fruit ripening, and senescence. This lipid-derived plant hormone, which is structurally similar to *prostaglandins* in animals (see Chapter 49), is also produced in response to the presence of insect pests and disease-causing organisms.

Jasmonic acid triggers the production of enzymes that confer an increased resistance against herbivorous (plant-eating) insects. For example, caterpillar-infested tomato plants release volatile jasmonic acid into the air that attracts natural caterpillar enemies, such as parasitic wasps; the wasps lay their eggs on the caterpillars' bodies. When the eggs hatch, the wasp larvae consume, and ultimately kill, the host insects. In one study, treating plants with jasmonic acid increased parasitism on caterpillar pests twofold over control fields in which the plants did not have jasmonic acid applications.

Jasmonic acid may be of practical value in controlling certain insect pests without the use of chemical pesticides.

Biologists have made progress in identifying key aspects of the jasmonic acid signaling pathway. Interestingly, the jasmonic acid signaling pathway includes ubiquitin, which was discussed earlier in the chapter in relation to auxin (see Fig. 38-4). As in the auxin signaling pathway, the ubiquitin tags in the jasmonic acid signaling pathway cause degradation of transcription repressors, thereby altering gene expression.

Methyl salicylate may induce systemic acquired resistance

For centuries, people chewed willow (*Salix*) bark to treat headaches and other types of pain. **Salicylic acid** was first extracted from willow bark and is chemically related to aspirin (acetylsalicylic acid). More recently, biologists have shown that salicylic acid helps plants defend against insect pests and pathogens such as viruses. When a plant is under attack, the concentration of salicylic acid increases, and it spreads systemically throughout the plant.

Based on current research, biologists think that *methyl salicylate*, a derivative of salicylic acid also known as *oil of wintergreen*, binds to a cell receptor, triggering a signal transduction pathway that switches on genes. These genes code for proteins that establish systemic acquired resistance to fight infection and promote wound healing.

Plants also use methyl salicylate, which is volatile, to signal nearby plants. Tobacco plants infected with tobacco mosaic virus release methyl salicylate into the air. When nearby healthy plants receive the airborne chemical signal, they begin synthesizing antiviral proteins that enhance their resistance to the virus.

CHECKPOINT 38.4

- You observe necrotic lesions on the leaves of a plant in your garden. Are they more likely due to a hypersensitive response or to systemic acquired resistance (SAR)? Explain your answer.

Summary: Focus on Learning Objectives

38.1 Tropisms (page 804)

1 Describe phototropism, gravitropism, and thigmotropism.

- **Tropisms** are directional growth responses. **Phototropism** is growth in response to the direction of light. **Gravitropism** is growth in response to the influence of gravity. **Thigmotropism** is growth in response to contact with a solid object.

38.2 Plant Hormones and Development (page 805)

2 Describe a general mechanism of action for plant hormones, using auxin as your example.

- Plants produce and respond to **hormones**, organic molecules that act as highly specific chemical signals to elicit a variety of responses that regulate growth and development.
- Many plant hormones bind to *enzyme-linked receptors* located in the plasma membrane; the hormone binds to the receptor, triggering an enzymatic reaction of some sort. The receptor for auxin, which is located in the cytosol or nucleus, binds to auxin. This catalyzes the attachment of ubiquitin to a repressor protein, targeting it for destruction. When genes repressed by those proteins are then expressed, changes in cell growth and development result.

3 Describe early auxin experiments involving phototropism.

- Charles Darwin and his son Francis performed phototropism experiments in the 1870s on grass seedlings. When they covered the coleoptile tip, the plant did not bend. When they removed the coleoptile tip, bending did not occur. When the bottom of the coleoptile was shielded from the light, the coleoptile bent. The Darwins concluded that some substance is transmitted from the upper to the lower part that causes the plant to bend.
- In the 1920s, Frits Went isolated the phototropic hormone from oat coleoptiles by removing the coleoptile tips and placing them on agar blocks. Normal growth resumed when he put one of these agar blocks squarely on a decapitated coleoptile; the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile. Went named this substance auxin.

4 List several ways that each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, abscisic acid, and brassinosteroids.

- **Auxin** is involved in cell elongation; tropisms; **apical dominance**, the inhibition of axillary buds by the apical meristem; and fruit development. Auxin also stimulates root development on stem cuttings.
- **Gibberellins (GA)** are involved in stem elongation, flowering, and germination.
- **Cytokinins** promote cell division and differentiation; delay **senescence**, the natural aging process; and interact with auxin and ethylene in apical dominance. Cytokinins induce cell division in **tissue culture**, a technique in which cells are isolated from plants and grown in a nutrient medium.
- **Ethylene** plays a role in ripening fruits; apical dominance; leaf abscission; wound response; **thigmomorphogenesis**, a developmental response to mechanical stressors such as wind; and senescence.

- **Abscisic acid (ABA)** is an environmental stress hormone involved in stomatal closure caused by water stress and in seed **dormancy**, a temporary state of reduced physiological activity.
- Plant steroids known as **brassinosteroids (BRs)** are involved in several aspects of plant growth and development, such as cell division, cell elongation, light-induced differentiation, seed germination, and vascular development.

38.3 Light Signals and Plant Development (page 813)

5 Explain how varying amounts of light and darkness induce flowering.

- **Photoperiodism** is any response of plants to the duration and timing of light and dark. Flowering is a photoperiodic response in many plants. **Short-day plants** detect the lengthening nights of late summer or fall and flower at that time. **Long-day plants** detect the shortening nights of spring and early summer and flower at that time. **Intermediate-day plants** flower when exposed to days and nights of intermediate length.

6 Describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.

- The photoreceptor in photoperiodism is **phytochrome**, a family of about five blue-green pigments. Each type of phytochrome has two forms, **Pr** and **Pfr**, named by the wavelength of light they absorb. Pfr is the active form, triggering or inhibiting physiological responses such as flowering, **shade avoidance**, and a light requirement for germination.
- The pathway in phytochrome **signal transduction** begins when inactive phytochrome in the cytoplasm absorbs red light and is converted into the active form, Pfr, which moves into the nucleus. There, phytochrome binds to the transcription factor PIF3 (phytochrome-interacting factor) and activates or represses the transcription of light-responsive genes.

7 Define circadian rhythm and give an example.

- A **circadian rhythm** is a regular period in an organism's growth or activities that approximates the 24-hour day and is reset by the rising and setting of the sun. Two examples of circadian rhythms are the opening and closing of stomata and *sleep movements*.

8 Distinguish between phytochrome and cryptochrome.

- Both phytochrome and **cryptochrome** are photoreceptors that sometimes interact to regulate similar responses, such as resetting the biological clock. Phytochrome strongly absorbs red light, whereas cryptochrome absorbs blue and ultraviolet-A light.

38.4 Responses to Herbivores and Pathogens (page 817)

9 Distinguish between the hypersensitive response and systemic acquired resistance.

- Each plant cell has an innate immune system to fight against local infections. A *hypersensitive response* seals off the infected area, causing it to die. These dead areas prevent or slow the spread of the initial infection.
- **Systemic acquired resistance (SAR)** is a buildup of long-lasting, enhanced resistance throughout the plant. Systemic acquired resistance is broad spectrum (against many types of pathogens).

Test Your Understanding

Know and Comprehend

1. In the signal transduction process for the hormone auxin, the molecule ubiquitin (a) absorbs blue light (b) becomes phosphorylated (c) tags certain proteins for destruction (d) interacts antagonistically with gibberellins (e) binds to a receptor in the plant cell's plasma membrane
2. When you prune shrubs to make them "bushier"—that is, to prevent apical dominance—you are affecting the distribution and action of which plant hormone? (a) auxin (b) jasmonic acid (c) salicylic acid (d) ethylene (e) abscisic acid
3. Research on a fungal disease of rice provided the first clues about the plant hormone (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
4. This plant hormone interacts with auxin during the formation of plant organs in tissue culture. (a) florigen (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
5. The stress hormone that helps plants respond to drought is (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
6. This hormone promotes seed dormancy. (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
7. The three classes of photoreceptors that enable plants to sense the presence and duration of light are (a) phytochrome, cryptochrome, and circadian rhythms (b) chlorophyll, photosynthesis, and photoperiodism (c) phytochrome, photoperiodism, and chlorophyll (d) phytochrome, cryptochrome, and phototropin (e) phototropin, photosynthesis, and photoperiodism
8. Pfr, the active state of _____, forms when red light is absorbed. (a) photosystem I (b) phytochrome (c) far-red light (d) phototropin (e) cryptochrome
9. Which photoreceptor(s) is/are implicated in resetting the biological clock? (a) phytochrome only (b) cryptochrome only (c) phototropin only (d) cryptochrome and gibberellin (e) phytochrome and cryptochrome
10. Which signaling molecule triggers the release of volatile substances that attract parasitic wasps to plant-eating caterpillars? (a) phytochrome (b) jasmonic acid (c) auxin (d) methyl salicylate (e) gibberellin

Apply and Analyze

11. Arrange the following steps in the correct order in the phytochrome signal transduction pathway: 1. red light; 2. light-responsive gene is switched on (or off); 3. movement of Pfr to nucleus; 4. conversion of Pr to Pfr; 5. formation of Pfr-PIF3 complex that is bound to promoter region

12. **PREDICT** State whether flowering in a short-day plant with a minimum critical night length of 14 hours would be expected to occur in the following situations. Explain each answer.
 - (a) The plant is exposed to 15 hours of daylight and 9 hours of uninterrupted darkness.
 - (b) The plant is exposed to 9 hours of daylight and 15 hours of darkness.
 - (c) The plant is exposed to 9 hours of daylight and 15 hours of darkness, with a 10-minute exposure to red light in the middle of the night.
13. **PREDICT** If you transplanted the short-day plant discussed in Question 12 to the Equator, would it flower? Explain your answer.

Evaluate and Synthesize

14. **EVOLUTION LINK** What adaptive advantages are conferred on a plant whose stems are positively phototropic and whose roots are positively gravitropic?
15. **EVOLUTION LINK** Explain why a plant with a mutation in one of its phytochrome genes that affects flowering time would be at an evolutionary disadvantage.
16. **INTERPRET DATA** Examine the figure. When the day length is 10 hours and the night length is 14 hours, what percentage of the plants flower? When the day length is 16 hours and the night length is 8 hours, what percentage of the plants flower? What is the critical night length for this plant?

17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Do you think that our expanding knowledge of the molecular basis of plant signaling molecules could improve agricultural productivity in the future? Explain your answer.

39 Animal Structure and Function: An Introduction

Animal species are dramatically diverse, with radically different body structures. For example, consider how different the elephant and the bird are, not only in size but also in body form and lifestyle (see photograph). Despite their differences, animal groups share many characteristics, including their relatively large size.

Why are most animals larger than bacteria, archaea, protists, and fungi? The answer may be related to *ecological niches*—the functional roles of a species within a community. By the time animals evolved, other organisms already occupied most available ecological niches. For new species to succeed, they had to displace others from a niche or adapt to a new one. Success in a new niche required a new body plan, and new body plans often required larger size. Increased size also provided more opportunity for capturing food. Predators are typically larger than their prey.

To grow larger than their bacterial and protist competitors, animals had to be multicellular. Recall that the size of a single cell is limited by the ratio of its surface area (plasma membrane) to its volume (see Chapter 4). The plasma membrane needs to be large enough relative to the cell's volume to permit passage of materials into and out of the cell so that the conditions necessary for life can be maintained. In a multicellular animal, each cell has a large enough ratio of surface area to volume to effectively regulate its internal environment. Individual cells live and die, and they are replaced while the organism continues to maintain itself and thrive. The number of cells, not their individual sizes, is mainly responsible for the size of an animal.

In unicellular organisms such as bacteria and many protists, the single cell carries on all the activities necessary for life. Recall that unicellular and small, flat organisms depend on diffusion for many life processes, including gas exchange and disposal of metabolic wastes. One reason they can be small is that they do not require complex organ systems like multicellular organisms do.

KEY CONCEPTS

- 39.1** Cells make up tissues, various types of tissues make up organs, and tissues and organs working together make up organ systems. The main types of tissues found in animals are epithelial, connective, muscle, and nervous tissues.
- 39.2** Homeostatic mechanisms are mainly negative feedback systems that maintain a relatively stable internal environment.
- 39.3** Thermoregulation is the process of maintaining homeostasis of body temperature despite changes in surrounding (or internal) temperature.

PHOTO: Larger body size does not mean bigger cells. The cells of the elephant mother, her calf, and the bird on the young elephant's back are all about the same size. The elephants are larger than the bird because their genes specify that their bodies consist of a larger number of cells. The cells of the young elephant will continue to multiply until it reaches adult size (African elephant, *Loxodonta africana*). MaggyMeyer/Shutterstock.com

In this chapter we focus on the basic form and function of the animal body. **Anatomy** is the study of an organism's structure. **Physiology** is the study of how the body functions. Remember that in biological systems, structures are adapted to function at every level of organization. Notice the many examples of this basic principle as we describe the types and functions of tissues and the principal organ systems of animals. In this chapter we also discuss the important concept of *homeostasis*, using regulation of body temperature as an example. In the following chapters, we discuss how organ systems work together to maintain homeostasis as animals carry out their many life processes.

39.1 Tissues, Organs, and Organ Systems

LEARNING OBJECTIVES

- 1 Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous tissues.
- 2 Compare the main types of epithelial tissue and describe their functions.
- 3 Compare the main types of connective tissue and describe their functions.
- 4 Contrast the three types of muscle tissue and describe their functions.
- 5 Relate the structure of the neuron to its function.
- 6 Briefly describe the organ systems of a mammal and summarize the functions of each organ system.

In a multicellular organism, cells specialize to perform specific tasks. Recall from Chapter 1 that cells organize to form *tissues*, and tissues associate to form *organs* such as the heart or stomach. Groups of tissues and organs make up the *organ systems* of a complex *organism*. Billions of cells organize to form the tissues, organs, and organ systems of a lobster, a crocodile, or an elephant.

A **tissue** consists of a group of closely associated, similar cells that carry out specific functions. Biologists classify animal tissues as epithelial, connective, muscle, or nervous tissue. Classification of tissues depends on their structure and origin. Each kind of tissue is composed of specialized cells with specific sizes, shapes, and arrangements. Some tissues are specialized to transport materials, whereas others contract, enabling the animal to move. Still others secrete hormones that regulate metabolic processes. Structure and function are closely linked at every level of organization. As we discuss each tissue type, notice the relationship between its form and its function. Notice also how biological systems continuously interact.

Epithelial tissues cover the body and line its cavities

Epithelial tissue (also called *epithelium*) consists of cells fitted tightly together to form a continuous layer, or sheet, of cells. One surface of the sheet is typically exposed because it covers the body (outer layer of the skin) or lines a cavity, such

as the cavity (*lumen*) of the intestine. The other surface of an epithelial layer attaches to the underlying tissue by a noncellular **basement membrane** consisting of tiny *fibers* and nonliving polysaccharide material that the epithelial cells produce.

Epithelial tissue forms the outer layer of the skin and the linings of the digestive, respiratory, excretory, and reproductive tracts. As a result, everything that enters or leaves the body must cross at least one layer of epithelium. Food taken into the mouth and swallowed is not really “inside” the body until it is absorbed through the epithelium of the digestive tract and enters the blood. To a large extent, the permeabilities of the various epithelial tissues regulate the exchange of substances between the different parts of the body as well as between the animal and the external environment.

Epithelial tissues perform many functions, including protection, absorption, secretion, and sensation. The epithelial layer of the skin, the **epidermis**, covers the entire body and protects it from mechanical injury, chemicals, bacteria, and fluid loss. The epithelial tissue lining the digestive tract absorbs nutrients and water into the body. Some epithelial cells form **glands** that secrete cell products such as hormones, enzymes, or sweat. Other epithelial cells are sensory receptors that receive information from the environment. For example, epithelial cells in taste buds and in the nose specialize as chemical receptors.

TABLE 39-1 illustrates the main types of epithelial tissue, indicates their locations in the body, and describes their functions (pages 824–825). We can distinguish three types of epithelial cells based on their shape. *Squamous* epithelial cells are thin, flat cells shaped like flagstones. *Simple squamous epithelium* lines the blood vessels and the air sacs in the lungs. *Cuboidal* epithelial cells are short cylinders. When you look at them from the side, they appear cube-shaped, like dice. Actually, each cuboidal cell is typically hexagonal in cross section, making it an eight-sided polyhedron. *Simple cuboidal epithelium* lines the kidney tubules.

When viewed from the side, *columnar* epithelial cells look like columns or cylinders. The nucleus is usually located near the base of the cell. Viewed from above or in cross section, these cells often appear hexagonal. On its free surface, a columnar epithelial cell may have cilia that beat in a coordinated way, moving materials over the tissue surface. Most of the upper respiratory tract is lined with ciliated *columnar epithelium* that moves particles of dust and other foreign material away from the lungs.

Epithelial tissue is also classified by number of layers. *Simple epithelium* is composed of one layer of cells. It is usually located where substances are secreted, excreted, or absorbed, or where materials diffuse between compartments. For example, simple squamous epithelium lines the air sacs in the lungs. The structure of this thin tissue allows diffusion of gases in and out of air sacs.

Stratified epithelium, which has two or more layers, protects underlying tissues. For example, stratified squamous epithelium, which makes up the outer layer of your skin, is continuously sloughed off during normal wear and tear. It must also continuously regenerate. The cells of *pseudostratified epithelium* appear layered, but they are not. Although all its cells rest on a basement membrane, not every cell extends to the exposed surface of the tissue. This arrangement gives the

impression of two or more cell layers. Some of the respiratory passageways are lined with pseudostratified epithelium equipped with cilia.

The lining of blood and lymph vessels is called endothelium. Endothelial cells have a different embryonic origin from “true” epithelium. However, these cells are structurally similar to squamous epithelial cells and can be included in that category.

Glands are made of epithelial cells

A **gland** consists of one or more epithelial cells specialized to produce and secrete a product such as sweat, milk, mucus, wax, saliva, hormones, or enzymes (FIG. 39-1). Epithelial tissue lining the cavities and passageways of the body typically has some specialized mucus-secreting cells called **goblet cells**. The mucus lubricates these surfaces, offers protection, and facilitates the movement of materials.

Glands are classified as exocrine or endocrine. **Exocrine glands**, like goblet cells and sweat glands, secrete their products onto a free epithelial surface, typically through a duct (tube). **Endocrine glands** lack ducts. These glands release their products, called **hormones**, into the **interstitial fluid** (tissue fluid) or blood. Hormones are typically transported by the cardiovascular system. (Endocrine glands are discussed in Chapter 49.)

Epithelial cells form membranes

An *epithelial membrane* consists of a sheet of epithelial tissue and a layer of underlying connective tissue. Types of epithelial membranes include mucous membranes and serous membranes. A **mucous membrane**, or *mucosa*, lines a body cavity that opens to the outside of the body, such as the digestive tract or respiratory tract. Goblet cells in the epithelial layer secrete mucus that lubricates the tissue and protects it from drying.

A **serous membrane** lines a body cavity that does not open to the outside of the body. It consists of simple squamous epithelium over a thin layer of loose connective tissue. This type of membrane secretes fluid into the cavity it lines. Examples of serous membranes are the pleural membranes lining the pleural cavities around the lungs and the pericardial membranes lining the pericardial cavity around the heart.

Connective tissues support other body structures

Almost every organ in the body has a framework of **connective tissue** that supports and cushions it. Compared with epithelial tissues, connective tissues contain relatively few cells. Connective tissue cells are embedded in an extensive **intercellular substance** consisting of threadlike, microscopic **fibers** scattered throughout a **matrix**, a thin gel of polysaccharides that the cells secrete. The structure and properties of the intercellular substance help determine the nature and function of each kind of connective tissue.

Figure 39-1 Glands

A gland consists of one or more epithelial cells.

Connective tissue typically contains three types of fibers: collagen, elastic, and reticular. *Collagen fibers*, the most numerous type, are made of **collagens**, a group of fibrous proteins found in all animals (see Fig. 3-23b). Collagens are the most abundant proteins in mammals, accounting for about 25% of their total protein mass. Collagen is very tough (meat is tough because of its collagen content). The tensile strength (ability to stretch without tearing) of collagen fibers is comparable to that of steel. Collagen fibers are wavy and flexible, allowing them to remain intact when tissue is stretched.

Elastic fibers branch and fuse to form networks. They can be stretched by a force and then (like a stretched rubber band) return to their original size and shape when the force is removed. Elastic fibers, composed of the protein elastin, are an important component of structures that must stretch.

Reticular fibers are very thin, branched fibers that form delicate networks joining connective tissues to neighboring tissues. Reticular fibers consist of collagen and some glycoprotein.

The cells of various kinds of connective tissues differ in their shapes and structures and in the kinds of fibers and

Table 39-1 Epithelial Tissues

Nuclei of squamous epithelial cells

Ed Reschke/Getty Images

Simple Squamous Epithelium

Main Locations

Air sacs of lungs; lining of blood vessels

Functions

Passage of materials where little or no protection is needed and where diffusion is major form of transport

Description and Comments

Cells are flat and arranged as single layer

LM of simple squamous epithelium.

Nuclei of cuboidal epithelial cells Lumen of tubule

Ed Reschke/Peter Arnold/Getty Images

Simple Cuboidal Epithelium

Main Locations

Linings of kidney tubules; gland ducts

Functions

Secretion and absorption

Description and Comments

Single layer of cells; LM shows cross section through tubules; from the side each cell looks like a short cylinder; some have microvilli for absorption

LM of simple cuboidal epithelium.

Goblet cell Nuclei of columnar cells

Ed Reschke/Getty Images

Simple Columnar Epithelium

Main Locations

Linings of much of digestive tract and upper part of respiratory tract

Functions

Secretion, especially of mucus; absorption; protection; moves layer of mucus

Description and Comments

Single layer of columnar cells; highly developed Golgi complex; often ciliated; goblet cells secrete mucus

LM of simple columnar epithelium.

Continued

LM of stratified squamous epithelium.

Stratified Squamous Epithelium*Main Locations*

Skin; mouth lining; vaginal lining

Functions

Protection only; little or no absorption or transit of materials; outer layer continuously sloughed off and replaced from below

Description and Comments

Several layers of cells, with only the lower ones columnar and metabolically active; division of lower cells causes older ones to be pushed upward toward surface, becoming flatter as they move

LM of pseudostratified columnar epithelium, ciliated.

Pseudostratified Epithelium*Main Locations*

Some respiratory passages; ducts of many glands

Functions

Secretion; protection; moves layer of mucus

Description and Comments

Ciliated, mucus-secreting, or with microvilli; comparable in many ways to columnar epithelium except that not all cells are the same height; so, although all cells contact the same basement membrane, the tissue appears stratified

matrices they secrete. **Fibroblasts** are connective tissue cells that produce the fibers, as well as the protein and carbohydrate complexes, of the matrix. Fibroblasts release protein components that become arranged to form the characteristic fibers. These cells are especially active in developing tissues and are important in healing wounds. As tissues mature, the number of fibroblasts decreases, and they become less active. **Macrophages**, the body's scavenger cells, commonly wander

through connective tissues, cleaning up cell debris and phagocytosing foreign matter, including bacteria.

Some of the main types of connective tissue are (1) loose and dense connective tissues; (2) elastic connective tissue; (3) reticular connective tissue; (4) adipose tissue; (5) cartilage; (6) bone; and (7) blood, lymph, and tissues that produce blood cells. These tissues vary widely in their structural details and in the functions they perform (TABLE 39-2).

Table 39-2 Connective Tissues

Loose Connective Tissue

Main Locations

Everywhere that support must be combined with elasticity, such as subcutaneous tissue (the layer of tissue beneath the dermis of the skin)

Functions

Support; reservoir for fluid and salts

Description and Comments

Fibers produced by fibroblast cells embedded in semifluid matrix; other types of cells, e.g., macrophages, present

LM of loose connective tissue.

Dense Connective Tissue

Main Locations

Tendons; many ligaments; dermis of skin

Functions

Support; transmits mechanical forces

Description and Comments

Collagen fibers may be regularly or irregularly arranged

LM of dense connective tissue.

Elastic Connective Tissue

Main Locations

Structures that must both expand and return to their original size, such as lung tissue and large arteries

Function

Confers elasticity

Description and Comments

Branching elastic fibers interspersed with fibroblasts

LM of elastic connective tissue.

Reticular Connective Tissue

Main Locations

Framework of liver; lymph nodes; spleen

Function

Support

Description and Comments

Consists of interlacing reticular fibers

LM of reticular connective tissue.

Continued

Table 39-2 Connective Tissues (*continued*)

Adipose Tissue

Main Locations

Subcutaneous layer; forms protective pads around certain internal organs

Functions

Stores fat; insulation; supports organs such as mammary glands, kidneys

Description and Comments

Fat cells are star shaped at first; fat droplets accumulate until typical ring-shaped cells are produced

LM of adipose tissue.

Cartilage

Main Locations

Supporting skeletons in sharks and rays; ends of bones in mammals and some other vertebrates; supporting rings in wall of trachea; tip of nose; external ear

Function

Flexible support

Description and Comments

Cells (chondrocytes) separated from one another by intercellular substance; cells occupy lacunae

LM of cartilage.

Bone

Main Locations

Forms skeletal structure in most vertebrates

Functions

Supports and protects internal organs; calcium reservoir; skeletal muscles attach to bones

Description and Comments

Cells (osteocytes) in lacunae; in compact bone lacunae embedded in lamellae, concentric circles of matrix surrounding Haversian canals

LM of bone.

Blood

Main Locations

Within heart and blood vessels of circulatory system

Functions

Transports oxygen, nutrients, wastes, and other materials; white blood cells defend against disease organisms

Description and Comments

Consists of red blood cells, white blood cells, and platelets dispersed in fluid matrix (plasma)

LM of blood.

Loose connective tissue is the most widely distributed connective tissue in the vertebrate body. Together with adipose tissue, loose connective tissue forms the subcutaneous (below the skin) layer that attaches skin to the muscles and other structures beneath. Nerves, blood vessels, and muscles are wrapped in loose connective tissue. This tissue also forms a thin filling between body parts and serves as a reservoir for fluid and salts. Loose connective tissue consists of fibers running in all directions through a semifluid matrix. Its flexibility permits the parts it connects to move.

Dense connective tissue, found in the dermis (lower layer) of the skin, is very strong, but is somewhat less flexible than loose connective tissue. Collagen fibers predominate. **Tendons**, the cords that connect muscles to bones, and **ligaments**, the cables that connect bones to one another, consist of dense connective tissue in which collagen bundles are arranged in a definite pattern.

Elastic connective tissue consists mainly of bundles of parallel elastic fibers. This tissue is found in structures that must expand and then return to their original size, such as lung tissue and the walls of large arteries.

Reticular connective tissue is composed mainly of interlacing reticular fibers. It forms a supporting internal framework in many organs, including the liver, spleen, and lymph nodes.

The cells of **adipose tissue** store fat and release it when fuel is needed for cellular respiration. Adipose tissue is found in the subcutaneous layer and in tissue that cushions internal organs.

The supporting skeleton of a vertebrate is made of cartilage or of both cartilage and bone. **Cartilage** is the supporting skeleton in the embryonic stages of all vertebrates. In most vertebrates bone replaces cartilage during development. However, cartilage remains in some supporting structures. In humans, for example, cartilage is found in the external ear, the supporting rings in the walls of the respiratory passageways, the tip of the nose, the ends of some bones, and the discs that serve as cushions between the vertebrae.

Cartilage is firm yet elastic. Its cells, called **chondrocytes**, secrete a hard, rubbery matrix that surrounds them. They also secrete collagen fibers, which become embedded in the matrix and strengthen it. Chondrocytes eventually come to lie, singly or in groups of two or four, in small cavities in the matrix called *lacunae*. These cells remain alive and are nourished by nutrients and oxygen that diffuse through the matrix. Cartilage tissue lacks nerves, lymph vessels, and blood vessels.

Bone, the main vertebrate skeletal tissue, is like cartilage in that it consists mostly of matrix material. The bone cells, called **osteocytes**, are contained within lacunae. Osteocytes secrete and maintain the matrix (FIG. 39-2). Unlike cartilage, however, bone is a highly vascular tissue, with a substantial blood supply. Osteocytes communicate with one another by means of their long cytoplasmic extensions.

A typical bone has an outer layer of **compact bone** surrounding a filling of *spongy bone*. Compact bone consists of spindle-shaped units called **osteons**. Within each osteon, osteocytes are arranged in concentric layers of matrix called *lamellae*. In turn, the lamellae surround central microscopic channels known as **Haversian canals**, through which capillaries and nerves pass.

Bones are amazingly light and strong. Calcium salts of bone render the matrix very hard, and collagen prevents the bony matrix from being overly brittle. Most bones have

a large, central *marrow cavity* that contains a spongy tissue called *marrow*. Yellow marrow consists mainly of fat. Red marrow is the connective tissue in which blood cells are produced. We discuss bone in more detail in Chapter 40.

Blood is a circulating tissue that helps other parts of the body communicate and interact. Like other connective tissues, blood consists of specialized cells dispersed in an intercellular substance. In mammals blood consists of **red blood cells**, **white blood cells**, and **platelets**, all suspended within **plasma**, the liquid, noncellular part of the blood. In humans and other vertebrates, red blood cells contain the respiratory pigment that transports oxygen. White blood cells defend the body against disease-causing microorganisms (discussed in Chapter 45). Platelets, small fragments broken off from large cells in the bone marrow, play a key role in blood clotting. Plasma consists of water, proteins, salts, and a variety of soluble chemical messengers such as hormones that it transports from one part of the body to another. We discuss blood in Chapter 44.

Lymph tissue, which is important in immune functions, is a type of connective tissue with large numbers of lymphocytes, a type of white blood cell. Lymph tissue organizes to form small masses of tissue called lymph nodes and larger organs, including the tonsils and spleen. We discuss lymph tissue further in Chapters 44 and 45.

Muscle tissue is specialized to contract

Most animals move by contracting the long, cylindrical or spindle-shaped cells of **muscle** tissue. Muscle cells are called muscle fibers because of their length. Each **muscle fiber** contains many thin, longitudinal, parallel contractile units called **myofibrils**. Two proteins, **myosin** and **actin**, are the chief components of myofibrils. Myosin and actin play a key role in contraction of muscle fibers.

Many invertebrates have skeletal and smooth muscle. Vertebrates have three types of muscle tissue: skeletal, cardiac, and smooth (TABLE 39-3 on page 830). **Skeletal muscle** makes up the large muscle masses attached to the bones of the body. Skeletal muscle fibers are very long, and each fiber has many nuclei. The nuclei of skeletal muscle fibers lie just under the plasma membrane, which frees the entire central part of the skeletal muscle fiber for the myofibrils. This adaptation appears to increase the efficiency of contraction. When skeletal muscles contract, they move parts of the body. Skeletal muscle fibers are generally under voluntary control. In contrast, you do not normally contract your cardiac and smooth muscle fibers at will.

Light microscopy shows that both skeletal and cardiac fibers have alternating light and dark transverse stripes, or *striations*, that change their relative sizes during contraction. Striated muscle fibers contract rapidly but cannot remain contracted for a long period. They must relax and rest momentarily before contracting again. (Muscle contraction is discussed in Chapter 40.)

Cardiac muscle is the main tissue of the heart. When cardiac muscle contracts, the heart pumps the blood. The fibers of cardiac muscle join end to end, and they branch and rejoin to form complex networks. One or two nuclei lie within each fiber. A characteristic feature of cardiac muscle tissue is the presence of *intercalated discs*, specialized junctions where the fibers join.

Figure 39-2 Bone

Smooth muscle occurs in the walls of the digestive tract, uterus, blood vessels, and many other internal organs. Contraction of smooth muscle is necessary for these organs to perform certain functions. For example, smooth muscle contraction in the wall of the stomach and intestine moves food through the digestive tract. When smooth muscle in the walls of arterioles (small arteries) contracts, these blood vessels constrict, raising blood pressure. Each spindle-shaped smooth muscle fiber contains a single, central nucleus.

Nervous tissue controls muscles and glands

Nervous tissue consists of neurons and glial cells. **Neurons** are specialized for receiving and transmitting signals. **Glial cells** support and nourish the neurons, destroy pathogens, and modulate transmission of impulses (FIG. 39-3).

A typical neuron has a **cell body** containing the nucleus as well as two types of cytoplasmic extensions (discussed in Chapter 41). **Dendrites** are cytoplasmic extensions specialized

Table 39-3 Muscle Tissues

	Skeletal	Cardiac	Smooth
Location	Attached to skeleton	Walls of heart	Walls of stomach, intestines, blood vessels, uterus
Type of control	Voluntary	Involuntary	Involuntary
Shape of fibers	Elongated, cylindrical, blunt ends	Elongated, cylindrical, fibers that branch and fuse	Elongated, spindle shaped, pointed ends
Striations	Present	Present	Absent
Number of nuclei per fiber	Many	One or two	One
Position of nuclei	Peripheral	Central	Central
Speed of contraction	Most rapid	Intermediate (varies)	Slowest
Resistance to fatigue (with repetitive contraction)	Least	Intermediate	Greatest

Skeletal muscle fibers

Cardiac muscle fibers

Smooth muscle fibers

for receiving signals and transmitting them to the cell body. The single **axon** transmits signals, called *nerve impulses*, away from the cell body. Axons range in length from 1 or 2 mm to more than a meter. Those extending from the spinal cord down the arm or leg in a human, for example, may be a meter or more in length.

Certain neurons receive signals from the external or internal environment and transmit them to the spinal cord and brain. Other neurons relay, process, or store information.

Figure 39-3 LM of nervous tissue

Neurons transmit information in the form of electrical and chemical signals. Glial cells support, protect, and nourish neurons. They also communicate and help regulate neural function.

Still others transmit signals from the brain and spinal cord to the muscles and glands. Neurons communicate at junctions called **synapses**. A **nerve** consists of a great many neurons bound together by connective tissue.

In this chapter we have focused on normal tissues. For a discussion of some abnormal tissues, see *Inquiring About: Unwelcome Tissues: Cancers*.

Tissues and organs make up the organ systems of the body

Tissues associate to form **organs**. Although an animal organ may be composed mainly of one type of tissue, other types are needed to support, protect, provide a blood supply, and transmit information. For example, the heart is mainly cardiac muscle tissue, but its chambers are lined with endothelium, and its walls contain blood vessels made of endothelium, smooth muscle, and connective tissue. The heart also has nerves that transmit information and help regulate the rate and strength of its contractions.

An organized group of tissues and organs that together perform a specialized set of functions make up an **organ system**. Working together in a very coordinated way, organ systems perform the functions required by the **organism**. We can identify 11 major organ systems that work together to carry out the physiological processes of a mammal: **integumentary system**, **skeletal system**, **muscular system**, **nervous system**, **endocrine system**, **cardiovascular system**, **lymphatic system** (which functions as the **immune system**), **respiratory system**, **digestive system**, **urinary system**, and **reproductive system**. **FIGURE 39-4** summarizes the principal organs and functions of each organ system.

Inquiring About

Unwelcome Tissues: Cancers

A **neoplasm** (“new growth”), or **tumor**, is an abnormal growth of cells. A neoplasm may be benign (“kind”) or malignant (cancerous). A benign neoplasm tends to grow slowly, and its cells stay together. Because benign tumors form masses with distinct borders, they can typically be removed surgically. A **malignant** (“wicked”) **neoplasm**, or **cancer**, typically grows much more rapidly and invasively than a benign tumor.

In Chapter 17 you learned that cancer results from abnormal expression of specific genes critical for cell division (see Fig. 17-20). Most cancer cells divide rapidly and in an uncontrolled way. Unlike normal cells, which respect one another’s boundaries and form tissues in an orderly, organized manner, cancer cells multiply chaotically and infiltrate normal tissues. They no longer receive or respond appropriately to signals from surrounding cells; communication is lacking (see figure).

When cancer cells multiply, they invade normal tissues and interfere with their functions. This SEM shows a mass of malignant cells (pink) in a pulmonary air sac (center). Cancer cells that have separated from the main tumor can be seen in other air sacs. Microvilli on the surface of the cancer cells give them a fuzzy appearance.

Unlike the cells of benign neoplasms, cancer cells do not retain normal structural features. When a cancer cell multiplies, all the cells derived from it are also abnormal. Most human cancers originate in epithelial tissue and are

called **carcinomas**. This group includes breast, prostate, colon, lung cancer, and most ovarian cancers. Cancers that develop from connective tissues or muscle are referred to as **sarcomas**.

Death from cancer typically results from **metastasis**, migration of cancer cells through blood or lymph channels to other parts of the body. Once there, cancer cells multiply, forming new malignant neoplasms that interfere with the normal functions of the tissues being invaded. Cancer often spreads so rapidly and extensively that surgeons cannot locate or remove all the malignant masses.

Solid tumors, which account for more than 85% of cancer deaths, require blood vessels to ensure delivery of nourishment and oxygen. Some tumors grow to several millimeters in diameter and then enter a dormant stage, which may last for months or even years. Eventually, cancer cells release a chemical substance that stimulates nearby blood vessels to develop new capillaries. These blood vessels grow into the abnormal mass of cells. Nourished by its new blood supply, the neoplasm may grow rapidly. Newly formed blood vessels have leaky walls that provide a route for metastasis. Malignant cells enter the blood through these walls and are transported to new sites.

Worldwide, cancer causes more than seven million deaths each year. In the United States, cancer is the second leading cause of death. One in three people in the United States develops cancer at some time in his or her life. More than 1.7 million new cancer cases are diagnosed each year. Currently, the key to survival is early diagnosis and treatment with some combination of surgery, hormonal treatment, radiation therapy, chemotherapy, inhibitors that suppress development of new blood vessels, immunotherapy, and targeted therapies. Many treatments are under investigation, including new agents that inhibit the development of new blood vessels. Immunotherapy for cancer will be discussed in Chapter 45. Cancer is a large family of closely related diseases (there are hundreds of distinct varieties), and treatment must be tailored to the particular type of cancer.

Most cancers are thought to be triggered by **carcinogens**, cancer-producing agents, in the environment, and by diet and lifestyle, for example cigarette smoking. Alleles of some genes appear to affect an individual’s level of tolerance to carcinogens. You can decrease

your risk of developing cancer by following these recommendations:

1. Do not smoke or use tobacco. Smoking is responsible for more than 80% of lung cancer cases, and it increases the risk for many other cancers.
2. Avoid prolonged exposure to the sun. When in the sun, use sunscreen or sunblock. Exposure to the sun is responsible for almost all of the more than two million cases of skin cancer reported each year in the United States alone.
3. Eat a healthy diet, including fresh, unprocessed fruits, vegetables, and grains. Limit intake of red meat. Avoid smoked, salt-cured, and nitrite-cured foods. Limit intake of alcoholic beverages. Reduce intake of foods and drinks that contribute to weight gain. Obesity increases the risk of cancer.
4. Exercise. Physical inactivity has been linked with increased risk of colon, breast, and other cancers.
5. Avoid unnecessary exposure to X-rays.
6. Self-examination and screening can lead to early diagnosis. Beginning at age 50, both men and women should be screened for colorectal cancer. Detection and removal of polyps (benign growths that can become malignant) can prevent cancer.
7. Self-examination and screening for women includes examining their breasts each month and having regular mammograms after age 40. Cervical cancer can be prevented with regular screening tests, such as the Papanicolaou (Pap) and human papilloma virus (HPV) tests. Certain HPV strains cause cervical cancer; vaccines are available.
8. Men over age 55 should discuss with their doctor the benefits of screening for prostate cancer with the prostate-specific antigen (PSA) blood test.
9. Consider genetic testing. If you have a family history of certain cancers, you may be at higher risk genetically for cancer. Genetic tests are now available to determine if you have mutations in the *BRCA1* or *BRCA2* genes, which increase risk for breast, ovarian, and pancreatic cancers. Mutations in several other genes indicate increased risk for colon, uterine, stomach, and urinary tract cancer. If you are at increased risk for cancer, a genetic counselor can advise you of measures you can take to reduce that risk.

CHECKPOINT 39.1

- **CONNECT** What are the main differences in structure and function between epithelial tissue and connective tissue?
- What type of tissue lines the air sacs of the lungs? How is its structure adapted to its function?

- What are some differences between the three types of muscle tissue? How is the structure of each type adapted for its function?
- What are the main functions of each of the following organ systems: (1) respiratory, (2) urinary, and (3) endocrine? (Consult Figure 39-4 for help.)

Figure 39-4 The principal organ systems of the human body

(7) IMMUNE/LYMPHATIC SYSTEM

Lymphatic vessels, lymph, lymph nodes, spleen, thymus, tonsils. Returns excess tissue fluid to blood, absorbs lipids, defends against disease.

(8) RESPIRATORY SYSTEM

Lungs, air passageways. Supplies oxygen to blood, excretes carbon dioxide.

(9) DIGESTIVE SYSTEM

Digestive tract and glands that secrete digestive juices. Processes food, eliminates wastes.

(10) URINARY SYSTEM

Kidneys, urinary bladder, associated ducts. Kidneys remove metabolic wastes and excess materials from blood, produce urine. Helps regulate blood chemistry.

(11) MALE AND FEMALE REPRODUCTIVE SYSTEMS

Both consist of gonads and associated structures. Sexual reproduction; maintains secondary sex characteristics.

In a negative feedback system, the response of the integrator is opposite to the input of the sensor. For example, when the glucose concentration in the blood is too low, alpha cells in the pancreas secrete a hormone that increases glucose concentration.

Figure 39-5 Negative feedback

PREDICT If you drank a soda (high in carbohydrates), what would happen to the glucose concentration in your blood? How do you think your body would respond?

39.2 Regulating the Internal Environment

LEARNING OBJECTIVE

- 7 Define *homeostasis* and contrast negative and positive feedback systems.

To survive and function, animals must regulate the composition of the fluids that bathe their cells. They must maintain pH and internal temperature within relatively narrow limits. The body must also maintain the appropriate concentration of nutrients, oxygen, and other gases, ions, and compounds needed for metabolism at all times.

Cells, tissues, organs, and organ systems work together to maintain appropriate conditions in the body. The balanced internal environment is referred to as **homeostasis**. Homeostasis is a basic concept in physiology. First coined by U.S. physiologist Walter Cannon, the word *homeostasis* is derived from the Greek *homoios*, meaning “same,” and *stasis*, “standing.” Although the internal environment never really stays the same, it is a dynamic equilibrium in which conditions are maintained within narrow limits. We call this a **steady state**. The control processes that maintain these conditions are **homeostatic mechanisms**.

Stressors, changes in the internal or external environment that affect normal conditions within the body, continuously

challenge homeostasis. An internal condition that moves out of its homeostatic range (either too high or too low) causes **stress**. An organism functions effectively because homeostatic mechanisms continuously operate to manage stress.

Many animals are **conformers** for certain environmental conditions. Some of their internal states vary with changes in their surroundings. For example, most marine invertebrates conform to the salinity of the surrounding sea water. Mammals are superb **regulators**. They have complex homeostatic mechanisms that maintain relatively constant internal conditions despite changes in the outside environment. How do homeostatic mechanisms work? Many are **feedback systems**, sometimes called “biofeedback systems.”

Negative feedback systems restore homeostasis

In a **negative feedback system**, a change in some steady state (e.g., normal body temperature) triggers a response that counteracts, or reverses, the change. A **sensor** detects a change, a deviation from the normal condition or **set point**. The sensor signals an **integrator**, or control center. Based on the input of the sensor, the integrator activates homeostatic mechanisms that restore the steady state (FIG. 39-5). The response counteracts the inappropriate change, thereby restoring the steady state.

Note that in a negative feedback system, the response of the integrator is *opposite* (negative) to the output of the

sensor. When some condition varies too far from the steady state (either too high or too low), a control system using negative feedback brings the condition back to the steady state. For example, when the glucose concentration in the blood *decreases* below its homeostatic level, negative feedback systems *increase* its concentration. Most homeostatic mechanisms in the body are negative feedback systems.

Let us discuss heat regulation, a common example of a negative feedback system. The temperature-regulating system in the human body is somewhat similar to how you regulate temperature in your home. You might set a particular room temperature on your thermostat. If the temperature in the room falls, the thermometer in the thermostat acts as a sensor that detects a change, or deviation, from the set point (FIG. 39-6a). The thermometer sends a signal to the thermostat, which then acts as an integrator, or control center. The thermostat compares the sensor's input with the set point. The thermostat then signals the furnace, which is the **effector** in this system. An effector is the device, organ, or process that helps restore the steady state. The furnace increases its heat output, a corrective response that brings the room temperature back to the set point. When the thermometer no longer detects a change from the set point, the thermostat and furnace are switched off.

As shown in FIGURE 39-6b, the negative feedback system that regulates body temperature works like a home thermostat. When body temperature decreases below normal limits, specialized nerve cells (sensors) signal the temperature-regulating center in the hypothalamus of the brain (the integrator). The

integrator activates effectors that bring the temperature back to the set point. The return to normal temperature signals the sensors, and the temperature-regulating center switches off the effectors.

A few positive feedback systems operate in the body

In a **positive feedback system**, a change in some steady state sets off a response that intensifies (rather than reverses) the changing condition. Although some positive feedback mechanisms are beneficial, they do not maintain homeostasis. For example, a positive feedback cycle operates during the birth of a baby. As the baby's head pushes against the cervix (lower part of uterus), a reflex action causes the uterus to contract. The contraction forces the head against the cervix again, stimulating another contraction, and the positive feedback cycle repeats again and again until the baby is born. Some positive feedback sequences, such as those that deepen circulatory shock following severe hemorrhage, can disrupt steady states and lead to death. A simplified example is shown in

FIGURE 39-7.

Homeostatic mechanisms maintain the internal environment within the physiological limits that support life. As you continue your study of animal processes, you will learn many ways in which organ systems interact to maintain the steady state of the organism. In the next section, we discuss some specific homeostatic mechanisms that help regulate body temperature.

Figure 39-6 Negative feedback in temperature regulation

Note that the diagram in (b) is highly simplified. Figure 39-9 shows greater detail.

Key Point

Positive feedback intensifies the change taking place, moving conditions farther away from homeostasis; in some situations such as hemorrhage, the results can be fatal.

Figure 39-7 Positive feedback

In positive feedback, the changes that occur increase the deviation from the set point. Conditions move away from the normal range. Loss of blood decreases blood pressure. Less blood reaches the heart, so heart function decreases. The resulting decrease in cardiac output (the volume of blood pumped by the left ventricle of the heart into the aorta in 1 minute) further decreases blood pressure. Conditions move farther from homeostasis.

PREDICT What might happen if you could convert this positive feedback system to a negative feedback system?

CHECKPOINT 39.2

- Contrast negative and positive feedback systems.

39.3 Regulating Body Temperature

LEARNING OBJECTIVES

- 8 Compare the costs and benefits of being an ectotherm, and describe strategies ectotherms use to adjust their body temperature.
- 9 Compare the costs and benefits of being an endotherm, and describe strategies endotherms use to adjust their body temperature.
- 10 Describe strategies animals use to adjust to challenging temperature changes.

Many animals have elaborate homeostatic mechanisms for regulating body temperature. Some are physiological, and others are structural or behavioral. **Thermoregulation** is the process of maintaining body temperature within certain limits despite changes in the surrounding temperature. Animals produce heat as a byproduct of metabolic activities. Body temperature is determined by the rate at which heat is produced and the rate at which heat is lost to, or gained from, the outside environment.

An animal's structural, physiological, and behavioral strategies for maintaining body temperature may restrict the type of environment it can inhabit. Each species has an optimal environmental temperature range and is adapted to a specific environment. Some animals, such as snowshoe hares, snowy owls, and weasels, can survive in cold arctic regions. Others, such as the Cape ground squirrel, which inhabits South Africa, are adapted to hot tropical climates. Although some animals can survive at temperature extremes, most survive only within moderate temperature ranges.

Ectotherms absorb heat from their surroundings

Ectotherms are animals that depend on the environment for their body heat. Their body temperature is determined mainly by the changing temperature of their surroundings. Most of the heat for their thermoregulation comes from the sun. In contrast, **endotherms** have homeostatic mechanisms that maintain body temperature despite changes in the external temperature. You may be surprised to learn that most animals are ectotherms.

An ectotherm's metabolic rate tends to change with the weather. These animals have a far lower daily energy expenditure than endotherms because they do not maintain a high metabolic rate. They therefore survive on less food and convert more of the energy in their food to growth and reproduction than do endotherms. Ectothermy also has costs. One disadvantage is that daily and seasonal temperature conditions may limit their activity.

Many ectotherms use behavioral strategies to adjust body temperature. For example, lizards may keep warm by burrowing in the soil at night. During the day, lizards take in heat by basking in the sun, orienting their bodies to expose the maximum surface area to the sun's rays (**FIG. 39-8a**). Many animals migrate to warmer climates during the winter. Another behavioral strategy for regulating temperature is *hibernation*.

Some insects use a combination of structural, behavioral, and physiological mechanisms to regulate body temperature. The "furry" body of the moth helps conserve body heat. When a moth prepares for flight, it contracts its flight muscles with little movement of its wings. The metabolic heat generated enables the moth to sustain the intense metabolic activity needed for flight.

Endotherms derive heat from metabolic processes

Birds and mammals, as well as some species of fish (e.g., tuna and certain sharks) and some insects, are endotherms. The

Charles Martin

(a) Ectotherm. The iguana increases its body temperature by sunning itself. Photographed in Florida, where this green iguana (*Iguana iguana*) is an invasive, exotic species.

Charles Martin

(b) Endotherm. Great blue heron (*Ardea herodias*) spreads its wings, exposing more of its body to the sun's warmth. Birds regulate their temperature physiologically. However, as illustrated here, they also have behavioral adaptations that help maintain body temperature.

Figure 39-8 Behavioral adaptations for thermoregulation

most important benefit of endothermy is the high metabolic rate, which can be as much as six times higher than that of ectotherms. The constant body temperature of endotherms allows a higher rate of enzyme activity than is possible for ectotherms living in the same habitat. Endotherms also can respond more rapidly to internal and external stimuli than ectotherms. Although they can be active even in low winter temperatures, these animals must pay the high energy cost of thermoregulation even during times when they are inactive. You must maintain your body temperature even when you are asleep!

Endotherms have structural adaptations for maintaining body temperature. For example, the insulating feathers of birds, hair of mammals, and insulating layers of fat in birds and mammals reduce heat loss from the body. Birds and mammals also have behavioral adaptations for maintaining body temperature. The Cape ground squirrel positions its tail to shade its body from the direct rays of the sun. Elephants spray themselves with cool water.

Endotherms have a variety of physiological mechanisms for maintaining temperature homeostasis. They regulate heat production and regulate heat exchange with the environment. Most of their body heat comes from their own metabolic processes (see *Inquiring About: Electron Transport and Heat* in Chapter 8).

In mammals, receptors located in the hypothalamus of the brain and in the spinal cord regulate temperature. Heat from metabolic activities can be increased directly or can be increased indirectly by the action of hormones (such as thyroid hormones) that increase metabolic rate. In cold weather, many animals shiver, which contracts muscles, producing heat.

When body temperature rises, birds and many mammals pant, and some mammals sweat. These processes provide fluid for evaporation: the conversion of a liquid, such as sweat, to water vapor. (Recall from Chapter 2 that when molecules enter the vapor phase, they take their heat energy with them.) Heat transfers from the body to the surroundings, resulting in evaporative cooling.

In the human body, about 2.5 million sweat glands secrete sweat. As sweat evaporates from the skin surface, body temperature decreases. Constriction and dilation of capillaries in the skin are also homeostatic mechanisms for regulating body temperature.

In humans, when body temperature increases above normal, specialized nerve cells signal the temperature-regulating center in the hypothalamus (FIG. 39-9). This center sends messages by way of nerves to the sweat glands, which increase sweat secretion. At the same time, the hypothalamus sends messages to smooth muscle in the walls of blood vessels in the skin that cause them to dilate. More blood circulates through the skin, bringing heat to the body surface. The skin acts as a heat radiator that allows heat to radiate from the body surface into the environment. These homeostatic mechanisms help return body temperature to normal.

When body temperature decreases below normal, the hypothalamus signals the anterior pituitary gland to release a hormone that signals the thyroid gland. Secretion of thyroid

Figure 39-9 Regulation of temperature in the human body

The hypothalamus is the integrator that maintains homeostasis of body temperature by activating mechanisms that **(a)** cool or **(b)** warm the body in response to stressors.

hormones increases, which raises metabolic rate. Body tissues increase heat production. The hypothalamus also sends neural signals that cause blood vessels in the skin to constrict. As a result, less heat is brought to the body surface. In addition, nerves signal muscles to shiver, which increases body temperature. Endotherms also use behavioral strategies to regulate body temperature. For example, birds spread their wings, increasing the body surface exposed to the sun (**FIG. 39-8b**), and you can warm up by voluntarily moving your muscles.

Many animals adjust to challenging temperature changes

Animals adjust to seasonal changes, a process called **acclimatization**. A familiar example is the thickening of a dog's coat in the winter. As water temperature decreases during fall and winter, a trout's enzyme systems decrease their level of activity, allowing the trout to remain active at the lowest metabolic cost.

When stressed by cold, many small endotherms sink into **torpor**, a short-term state in which metabolic rate decreases, sometimes dramatically. Torpor saves the energy that the animal would use to maintain a high body temperature. Instead, body temperature decreases below normal levels. The decrease in body temperature is brought about by a decrease

in the temperature set point in the hypothalamus. Heart and respiratory rates decrease, and animals are less responsive to external stimulation. Daily torpor occurs in some small endotherms, such as hummingbirds and shrews. We can think of torpor as an adaptive hypothermia that helps animals survive during times of cold temperatures.

Hibernation is long-term torpor in response to winter cold and scarcity of food. Animals that hibernate store unsaturated fats to use as energy sources. **Estivation** is a state of torpor caused by lack of food or water during periods of high temperature. During estivation, some mammals retreat to their burrows. The cactus mouse enters a state of hibernation during the winter in response to cold and scarcity of food. In the summer, it estivates in response to lack of either food or water.

CHECKPOINT 39.3

- What are some costs and benefits of ectothermy? How do ectotherms adjust body temperature?
- What are some costs and benefits of endothermy?
- **VISUALIZE** How is body temperature regulated in humans? Draw a diagram to illustrate your answer.

Summary: Focus on Learning Objectives

39.1 Tissues, Organs, and Organ Systems (page 822)

1 Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous tissues.

- A **tissue** consists of a group of similarly specialized cells that associate to perform specific functions. **Epithelial tissue** (*epithelium*) forms a continuous layer, or sheet, of cells covering a body surface or lining a body cavity. Epithelial tissue functions in protection, absorption, secretion, and sensation.
- **Connective tissue** consists of relatively few cells separated by an **intercellular substance**, composed of **fibers** scattered throughout a **matrix**. The intercellular substance contains three types of fibers: collagen, elastic, and reticular.
- Connective tissue contains specialized cells such as **fibroblasts** and **macrophages**. Connective tissue joins other tissues of the body, supports the body and its organs, and protects underlying organs.
- **Muscle** tissue consists of cells specialized to contract. Each cell is an elongated muscle fiber containing many contractile units called **myofibrils**. **Nervous tissue** consists of elongated cells called neurons, specialized for transmitting impulses, and **glial cells**, which support and nourish the neurons.

2 Compare the main types of epithelial tissue and describe their functions.

- Epithelial cells may be *squamous*, *cuboidal*, or *columnar* in shape. Epithelial tissue may be *simple*, *stratified*, or *pseudostratified* (summarized in Table 39-1).
- *Simple squamous epithelium* lines blood vessels and the air sacs in the lungs; it permits exchange of materials by diffusion. *Simple cuboidal epithelium* and *columnar epithelium* line passageways and are specialized for secretion and absorption. *Stratified squamous epithelium* forms the outer layer of the skin and lines passageways into the body; it provides protection. *Pseudostratified epithelium* also lines passageways and protects underlying tissues.
- Some epithelial tissue is specialized to form **glands**. **Goblet cells** are unicellular glands that secrete mucus. Goblet cells are **exocrine glands** that secrete their product through a duct onto an exposed epithelial surface. In contrast, **endocrine glands** release hormones into the **interstitial fluid** or blood.
- An *epithelial membrane* consists of a sheet of epithelial tissue and a layer of underlying connective tissue. A **mucous membrane** lines a cavity that opens to the outside of the body. A **serous membrane** lines a body cavity that does not open to the outside.

3 Compare the main types of connective tissue and describe their functions.

- The cells of connective tissue are embedded in an intercellular substance that consists of microscopic *collagen fibers*, *elastic fibers*, and *reticular fibers* (thin branched fibers) scattered through a **matrix**, a thin gel of polysaccharides. **Loose connective tissue** consists of fibers running in various directions through a semifluid matrix; it forms a covering for nerves, blood vessels, and muscles.

- **Dense connective tissue** is strong but less flexible than loose connective tissue. It forms **tendons**, cords that connect muscles to bones, and **ligaments**, cables that connect bones to one another.
- Elastic connective tissue consists of bundles of parallel elastic fibers; it is found in lung tissue and in walls of large arteries. *Reticular connective tissue*, which consists of interlacing reticular fibers, forms a supporting framework for many organs.
- **Adipose tissue** is made up of fat cells; it is found along with loose connective tissue in subcutaneous tissue.
- **Cartilage** consists of **chondrocytes** that lie in lacunae, small cavities in a hard matrix. **Osteocytes** secrete and maintain the matrix of **bone**. Unlike cartilage, bone is quite vascular. Cartilage and bone form the skeleton of vertebrates.
- **Blood** and lymph are circulating tissues that help various parts of an animal communicate with one another. The intercellular substances of blood and lymph are more fluid than those of other tissues.

4 Contrast the three types of muscle tissue and describe their functions.

- **Skeletal muscle** is striated and under voluntary control. Each elongated, cylindrical **muscle fiber** has several nuclei. When skeletal muscles contract, they move parts of the body.
- **Cardiac muscle** is also striated, but its contractions are involuntary. Its elongated, cylindrical fibers branch and fuse; each fiber has one or two central nuclei. When this muscle contracts, the heart pumps the blood.
- **Smooth muscle** contracts involuntarily; its elongated, spindle-shaped fibers lack striations. Each fiber has a single central nucleus. Smooth muscle is responsible for movement of body organs; for example, it pushes food through the digestive tract.

5 Relate the structure of the neuron to its function.

- The elongated **neuron** is adapted for receiving and transmitting information. **Dendrites** receive signals and transmit them to the **cell body**. The **axon** transmits signals away from the cell body to other neurons or to a muscle or gland. A **synapse** is a junction between neurons.

6 Briefly describe the organ systems of a mammal and summarize the functions of each organ system.

- Tissues and **organs** work together, forming **organ systems**. In mammals 11 organ systems work together to carry out the functions required by the **organism**: the **integumentary**, **skeletal**, **muscular**, **nervous**, **endocrine**, **cardiovascular**, **lymphatic** (which functions as part of the **immune system**), **respiratory**, **digestive**, **urinary**, and **reproductive systems** (summarized in Figure 39-4). Each organ system functions to maintain homeostasis.

39.2 Regulating the Internal Environment (page 834)

7 Define homeostasis and contrast negative and positive feedback systems.

- **Homeostasis** is the balanced internal environment, or steady state. The control processes that maintain these conditions are **homeostatic mechanisms**, mainly **negative feedback systems**. When a stressor causes a change in some steady state, a response is triggered that counteracts

the change. A **sensor** detects the change, a deviation from the normal condition or **set point**. The sensor signals an **integrator**, or control center. Based on the output of the sensor, the integrator activates one or more **effectors**, organs or processes that restore the steady state.

- In a **positive feedback system**, a deviation from the steady state sets off a series of changes that intensifies (rather than reverses) the changes.

39.3 Regulating Body Temperature (page 836)

- 8 Compare the costs and benefits of being an ectotherm, and describe strategies ectotherms use to adjust their body temperature.

- Animals have structural, behavioral, and physiological strategies for **thermoregulation**, the process of maintaining body temperature within certain limits despite changes in the surrounding temperature.
- In **ectotherms** body temperature depends to a large extent on the temperature of the environment. A benefit of ectothermy is that very little energy is used to maintain metabolic rate. A disadvantage is that activity may be limited by daily and seasonal temperature conditions. Many ectotherms use behavioral strategies to adjust body temperatures.

- 9 Compare the costs and benefits of being an endotherm, and describe strategies endotherms use to adjust their body temperature.

- **Endotherms** have homeostatic mechanisms for regulating body temperature within a narrow range. The most important benefit of endothermy is a high metabolic rate. Another advantage is that constant body temperature allows a higher rate of enzyme activity. Many endotherms are active even in low winter temperatures. A disadvantage of endothermy is its high energy cost.

- 10 Describe strategies animals use to adjust to challenging temperature changes.

- **Acclimatization** is the process of adjustment to seasonal changes.
- When challenged by a drop in surrounding temperature, many small endotherms enter a state of torpor. **Torpor** is an adaptive hypothermia; body temperature is maintained below normal levels. **Hibernation** is long-term torpor in response to winter cold. **Estivation** is torpor caused by lack of food or water during summer heat.

Test Your Understanding

Know and Comprehend

1. Tissue that contains fibroblasts and a great deal of intercellular substance is (a) connective tissue (b) muscle tissue (c) nervous tissue (d) pseudostratified epithelium (e) simple squamous epithelium
2. Tissue that contracts and is striated and involuntary would most likely be found in (a) the leg (b) the wall of the stomach (c) the exocrine glands (d) body structures requiring very rapid contraction (e) the heart
3. Which organ system has the homeostatic function of helping regulate volume and composition of blood and body fluids? (a) integumentary (b) muscular (c) reproductive (d) urinary (e) exocrine
4. Most homeostatic functions in the body are maintained by (a) exocrine glands (b) negative feedback systems (c) set points (d) stressors (e) positive feedback systems
5. Which of the following is *not* true of torpor? (a) it is an adaptive state of low body temperature (b) the temperature set point in the hypothalamus decreases (c) metabolic rate increases (d) it is a strategy used by some endotherms (e) respiratory rate decreases
6. An ectotherm (a) has a higher rate of enzyme activity than a typical endotherm (b) has a variety of homeostatic mechanisms for regulating body temperature (c) depends on sensors in the hypothalamus to regulate temperature (d) may use behavioral strategies to help adjust body temperature (e) must expend more energy on thermoregulation than an endotherm

Apply and Analyze

7. **VISUALIZE** Draw (a) simple cuboidal epithelium lining a kidney tubule and (b) loose connective tissue.
8. **VISUALIZE** Draw a flowchart showing the relationship among organ systems, tissues, cells, and organs.
9. **PREDICT** Jim has lost a great deal of epithelium due to a chemical burn. What effects might this change have on his body and its ability to function?
10. **PREDICT** The intercellular substance of the connective tissue in a dog's skin is decreasing due to a rare disease. What effect might this change have on the dog's body?
11. **PREDICT** A high concentration of carbon dioxide in the blood and interstitial fluid results in more rapid breathing. What effect would rapid breathing have on homeostasis?

Evaluate and Synthesize

12. **EVOLUTION LINK** From an evolutionary perspective, why do you think most animals are ectotherms? (*Hint*: What are some benefits of ectothermy?)
13. **SCIENCE, TECHNOLOGY, AND SOCIETY** Imagine that you are a health care professional. If a patient told you that she had a family history of breast cancer, would you advise her to be genetically tested? Why or why not? What if you had a family history of cancer? Would you want to be tested?

40 Protection, Support, and Movement

KEY CONCEPTS

- 40.1** Many structures and processes have evolved in animals for protection, support, and movement. Epithelial coverings are adapted for protecting underlying tissues and may be specialized for gas exchange, sensory reception, secretion, or other functions.
- 40.2** Skeletal systems, whether they are hydrostatic skeletons, exoskeletons, or endoskeletons, are adapted for supporting and protecting the body and for transmitting mechanical forces important in movement.
- 40.3** Muscles are adapted for contracting; during contraction, energy from ATP is used to move muscle filaments so that the muscle shortens. Body parts move when muscles pull on them.

PHOTO: Grasshopper in midjump. This two-striped grasshopper (*Melanoplus bivittatus*) uses powerful muscles in its hind legs to catapult itself into the air. Insect muscles attach to the exoskeleton.
Michael Durham/Minden Pictures/Getty Images

In Chapter 39 we described animal tissues, organs, and organ systems, laying the foundation for the more detailed discussions in this and later chapters. Here we focus on epithelial coverings, skeletons, and muscles, structures that work together to protect, support, and move the body and its parts. In our survey of the animal kingdom (Chapters 30–32), we described many adaptations involving these structures. For example, we discussed how the arthropod *exoskeleton* contributes to the great biological success of insects. In this chapter we compare these systems in several animal groups and then focus on their structure and function in mammals.

The *epithelial coverings* of animals protect underlying tissues and have several other functions as well. One of the most interesting is secretion of peptides and other substances that kill harmful bacteria and certain other pathogens. Frogs and toads, in particular, secrete a variety of potent peptides that protect them against harmful bacteria, fungi, and protozoa. Secretions of the frog *Rana ridibanda* have been shown to kill “superbugs,” such as MRSA (methicillin-resistant *Staphylococcus aureus*; see Chapter 25). The skin of amphibians is a promising potential source of new antibiotics and other drugs.

Most animals are also protected by a *skeletal system*. Whether it is a fluid-filled compartment, a shell, or a system of bones, the skeletal system protects internal organs and provides support for the body. The skeletal system and *muscular system* work together to produce movement. Muscle tissue is specialized to contract. Although a few animals remain rooted to one spot, sweeping their surroundings with tentacles, most animals move from place to place in the environment (locomotion). Muscles responsible for locomotion anchor to the skeleton, which gives them something firm on which to act. In most

vertebrates, bones serve as levers that transmit the force necessary to move various parts of the body.

During the course of evolution, most animals have developed adaptations for dependable, rapid, and responsive movement. Animals creep, walk, run, jump, swim, or fly (see photograph). These adaptations enable them to find food and escape from predators. In complex animals, effective movement depends on the cooperation and interactions of several body systems, including the muscular, skeletal, nervous, circulatory, respiratory, and endocrine systems. The precisely regulated interactions among tissues, organs, and organ systems make complex function and maintenance of homeostasis possible. These interactions are a dynamic example of systems biology in action.

40.1 Epithelial Coverings

LEARNING OBJECTIVES

- 1 Compare the functions of the epithelial coverings of invertebrates and vertebrates.
- 2 Relate the structure of vertebrate skin to its functions.

Epithelial tissue covers all external and internal surfaces of the animal body. The structure and functions of the external epithelial covering are adapted to the animal's environment and lifestyle. However, in both invertebrates and vertebrates, epithelial coverings protect the body. Epithelial coverings may also be specialized for secretion, gas exchange, or temperature regulation and typically contain receptors that receive sensory signals from the environment.

Invertebrate epithelium may secrete a cuticle

In many invertebrates the outer epithelium is specialized to secrete protective or supportive layers of nonliving material. In insects and many other animals, the secreted material forms an outer covering called a **cuticle**. Some animals, including corals and mollusks, secrete a shell made mainly of calcium carbonate.

In many species the epithelium contains cells that secrete lubricants or adhesives. Such cells may release odorous secretions used for communication or for marking trails. In other species secretory cells produce toxins used for offense or defense. The earthworm epithelium secretes lubricating mucus that promotes efficient diffusion of gases across the body wall and reduces friction during movement through the soil. Epithelial cells may be modified as sensory cells that are selectively sensitive to light, chemical stimuli, or mechanical stimuli, such as contact with an object, or pressure.

Vertebrate skin functions in protection and temperature regulation

The **integumentary system** of vertebrates includes the skin and structures that develop from it. In many fishes, in some

reptiles, and in the ant-eating pangolin (a mammal; see Fig. 18-15c), skin has developed into a set of scales formidable enough to be considered armor. Even human skin has considerable strength. The thin, moist skin of many amphibians is adapted for gas exchange as well as for defense.

Derivatives of skin differ considerably among vertebrates. Fishes have bony or toothlike scales. Amphibians have naked skin covered with mucus, and some species are equipped with poison glands. Reptiles have epidermal scales, mammals have hair, and birds have feathers that provide even more effective insulation than fur. The feathers of birds and the fur of mammals are insulating structures that help maintain body temperature by trapping heat in the body. Skin and its derivatives are often brilliantly colored, which helps in communication, for example, in courtship rituals and in territorial displays.

In mammals, structures derived from skin include claws (modified as fingernails and toenails in primates), hair, sweat glands, oil (sebaceous) glands, and several types of sensory receptors that give mammals the ability to feel touch, pressure, temperature, and pain. The skin of mammals also contains mammary glands, specialized in females for secretion of milk.

In humans and other mammals, oil glands empty via short ducts into hair follicles. A *hair follicle* is the part of a hair below the skin surface, together with the surrounding epithelial tissue. Oil glands secrete *sebum*, a mixture of fats and waxes that inhibits the growth of harmful bacteria.

Although the skin of fishes, frogs, snakes, pelicans, and elephants appears very different, the basic structure of skin is the same in all vertebrates. The outer layer of skin, the **epidermis**, is a waterproof protective barrier. The epidermis consists of several strata, or sublayers. The deepest is **stratum basale**, and the most superficial is **stratum corneum** (FIG. 40-1). Pigment cells in stratum basale and in the dermis below produce **melanin**, a pigment that contributes to the color of the skin. In stratum basale, epithelial cells continuously divide and are pushed outward as other cells are produced below them. Epidermal cells mature as they move toward the skin surface.

As they move toward the body surface, epidermal cells manufacture **keratin**, an elaborately coiled protein that gives the skin considerable mechanical strength and flexibility. Keratin is insoluble and serves as a diffusion barrier for the body surface. As epidermal cells move through stratum corneum, they die. When they reach the outer surface of the skin, they wear off and must be continuously replaced.

Beneath the epidermis lies the **dermis**, a dense, fibrous connective tissue made up mainly of collagen fibers (see Fig. 40-1). Collagen imparts strength and flexibility to the skin. The dermis also contains blood vessels that nourish the skin and sensory receptors for touch, pain, and temperature. Hair follicles and, in most mammals, sweat glands are embedded in the dermis. In birds and mammals, the dermis rests on a layer of *subcutaneous tissue*. This tissue consists mainly of adipose tissue that insulates the body from outside temperature extremes.

In humans exposure to ultraviolet (UV) radiation—the short, invisible rays from the sun—causes the epidermis to thicken and stimulates pigment cells in the skin to produce melanin at an increased rate. Melanin is an important

Figure 40-1 Human integumentary system

The integumentary system of humans and other mammals is a complex organ system consisting of skin and structures, such as hair and nails, that develop from it. The outer layer of the skin, the epidermis, consists of several sub-layers, or strata.

protective screen against the sun because it absorbs some of the harmful UV rays. An increase in melanin causes the skin to darken. The suntan so prized by sun worshipers is actually a sign that the skin has been exposed to too much UV radiation. When the melanin cannot absorb all the UV rays, the skin becomes inflamed, or sunburned. Dark-skinned people have more melanin, so they suffer less sunburn, wrinkling, and skin cancer than lighter-skinned people. However, they still require protection from UV rays.

UV radiation damages DNA, causing mutations that lead to malignant transformation of cells (see Chapter 17). Skin cancer is the most common type of cancer in humans, and most cases of skin cancer are caused by excessive, chronic exposure to UV radiation. The incidence of *malignant melanoma*, the most lethal type of skin cancer, is increasing faster than any other type of cancer. Greater understanding of the Ras/ERK cell signaling pathway has led to research aimed at developing targeted drugs for treating melanoma. (Recall from Chapter 6 that this pathway is the main signaling cascade for cell division and differentiation. Also see Figure 17-20 in Chapter 17.)

CHECKPOINT 40.1

- **CONNECT** How are the body coverings of invertebrates and vertebrates alike?
- **CONNECT** How is the structure of vertebrate skin related to its specific functions?
- What properties does keratin give human skin?
- What is the function of melanin?

40.2 Skeletal Systems

LEARNING OBJECTIVES

- 3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.
- 4 Describe the main divisions of the vertebrate skeleton and identify the bones that make up each division.
- 5 Describe (or draw and label) the structure of a typical long bone and contrast the roles of osteoblasts and osteoclasts in bone remodeling.
- 6 Compare the main types of vertebrate joints.

In addition to having an epithelial covering, many animals are protected by a **skeletal system** that forms the framework of the body. The skeleton also functions in locomotion. Muscles typically act on hard structures such as chitin or bone. These skeletal structures *transmit* mechanical forces generated by muscle contraction and *transform* them into the variety of motions that animals make. Most invertebrates have *hydrostatic skeletons* or *exoskeletons*. (You may recall from Chapter 32 that echinoderms are an exception. These invertebrates have an endoskeleton consisting of calcium carbonate plates and spines.) Vertebrates have *endoskeletons* of cartilage or bone.

In hydrostatic skeletons body fluids transmit force

Many soft-bodied invertebrates have **hydrostatic skeletons** made of fluid-filled body compartments. Imagine an elongated balloon full of water. If you pull on the balloon, it lengthens and becomes thinner. It does the same if you squeeze it. Conversely, if you push the ends toward the center, the balloon shortens and thickens.

Many invertebrates, including most cnidarians, flatworms, annelids, and roundworms, have hydrostatic skeletons that work something like a balloon filled with water. Fluid in a closed compartment of the body is held under pressure. When muscles in the compartment wall contract, they push against the tube of fluid. Because fluids cannot be compressed, the force is transmitted through the fluid, changing the shape and movement of the body.

In *Hydra* and other cnidarians, cells of the two body layers can contract. The contractile cells in the outer epidermal layer lie longitudinally, whereas the contractile cells of the inner layer (the gastrodermis) are arranged circularly around the central body axis. The two groups of cells work in *antagonistic* fashion: what one can do, the other can undo. When the inner (circular) layer contracts, the hydra thins, and its fluid contents force it to lengthen (FIG. 40-2a). In contrast, when the epidermal (longitudinal) layer contracts, the hydra shortens. Due to the fluid in the gastrovascular cavity, force is transmitted so that the hydra thickens as well (FIG. 40-2b).

Mechanically, the hydra is a bag of fluid that acts as a hydrostatic skeleton. It transmits force when the contractile cells contract against it. Although technically not a closed compartment, the gastrovascular cavity functions as a hydrostatic skeleton because its opening is small. Hydrostatic skeletons permit only crude mass movements of the body or its appendages. Delicate movements are difficult because force tends to be transmitted equally in all directions throughout the entire fluid-filled body of the animal. For example, it is not easy for the hydra to thicken one part of its body while thinning another.

Figure 40-2 Hydrostatic skeleton

In *Hydra*, fluid in the gastrovascular cavity transmits force when contractile cells in the body wall contract against it. The longitudinally arranged contractile cells of *Hydra* are antagonistic to the cells arranged circularly around the body axis.

The more complex hydrostatic skeleton of the annelid worm lets it move with increased flexibility. An earthworm's body consists of a series of segments divided by transverse partitions, or septa (see Fig. 31-19). The septa isolate portions of the body cavity and the coelomic fluid they contain. This arrangement allows the hydrostatic skeleton of each segment to be largely independent. As a result, contraction of the circular muscle in the elongating anterior end does not interfere with the action of the longitudinal muscle in the segments at the posterior end.

You can find some examples of hydrostatic skeletons in invertebrates equipped with shells or endoskeletons and even in vertebrates with endoskeletons of cartilage or bone. For example, sea stars and sea urchins have an endoskeleton, but they move their tube feet by an ingenious adaptation of a hydrostatic skeleton (see Chapter 32). And the human penis becomes erect and stiff because of the turgidity of pressurized blood in its internal spaces.

Mollusks and arthropods have nonliving exoskeletons

In most animals the skeleton is a lifeless shell, or **exoskeleton**, deposited atop the outer epithelial covering. In mollusks the exoskeleton is a calcium carbonate shell secreted by the mantle, a thin sheet of epithelial tissue that extends from the body wall. The exoskeleton provides protection, a retreat used in emergencies. The bulk of the tasty, naked body is exposed at other times.

Exoskeletons of arthropods serve not only to protect but also to transmit forces. In this respect they are comparable to the skeletons of vertebrates. The arthropod exoskeleton is a nonliving **cuticle** that contains the polysaccharide **chitin**. This exoskeleton consists of large, thick, inflexible plates that completely cover the body. These plates are separated from one another by thin, flexible joints arranged segmentally. Enough joints are present to make the arthropod's body as flexible as those of many vertebrates. The arthropod exoskeleton is adapted to a vast variety of lifestyles, and parts of it are modified to function as specialized tools or weapons.

A disadvantage of the rigid arthropod exoskeleton is that to accommodate growth an arthropod must shed its exoskeleton and replace it with a new, larger one (FIG. 40-3). Recall from Chapter 31 that this process, called **molting**, or **ecdysis**, is characteristic of the **Ecdysozoa**, a major branch of invertebrates. During ecdysis, the animal is weak and vulnerable to predators.

Internal skeletons are capable of growth

Echinoderms and chordates have internal skeletons, or **endoskeletons**. Composed of living tissue, the endoskeleton grows along with the animal as a whole. This skeleton consists of plates or shafts of calcium-impregnated tissue (such as cartilage or bone). The echinoderm endoskeleton consists of spines and plates of calcium salts embedded in the body wall, beneath an epidermis that covers the body. This endoskeleton forms what amounts to an internal shell that provides support and protection (FIG. 40-4). Many echinoderm endoskeletons bear spines that project to the outer surface.

Figure 40-3 Ecdysis

A greengrocer cicada (*Magicicada*) requires 13 years to mature. It then emerges from the soil, climbs a tree, and sheds its exoskeleton prior to reproducing.

You are probably most familiar with the endoskeleton of vertebrates. This endoskeleton provides support and protection and transmits muscle forces. Members of class Chondrichthyes (sharks and rays) have skeletons of cartilage, but in most vertebrates the skeleton consists mainly of bone. Many bones form systems of levers that transmit muscle forces. Bones store calcium and are important in maintaining homeostatic levels of calcium in the blood.

The vertebrate skeleton has two main divisions

The two main divisions of the vertebrate skeleton are the axial and appendicular skeletons (**FIG. 40-5**). The *axial skeleton*, located along the central axis of the body, consists of the skull, vertebral column, ribs, and sternum (breastbone). The *appendicular skeleton* consists of the bones of the limbs (arms and legs) plus the bones making up the girdles that connect the limbs to the axial skeleton, the pectoral (shoulder) girdle, and most of the pelvic (hip) girdle.

The *skull*, the bony framework of the head, consists of the cranial and facial bones. In the human skull, 8 cranial bones enclose the brain, and 14 bones make up the facial portion of the skull. Several cranial bones that are single in the adult human result from the fusion of 2 or more bones that are separate in the fetus or newborn.

Figure 40-4 The echinoderm endoskeleton

Like other echinoderms, this sunflower sea star (*Pycnopodia* sp.) has a spiny surface. Its endoskeleton is composed of spines and plates of nonliving calcium salts embedded in the body wall. The endoskeleton provides support and protection.

The vertebrate spine, or **vertebral column**, supports the body and bears its weight. In humans it consists of 24 **vertebrae** and 2 bones composed of fused vertebrae: the *sacrum* and *coccyx*. The vertebral column consists of the *cervical* (neck) region, with 7 vertebrae; the *thoracic* (chest) region, with 12 vertebrae; the *lumbar* (back) region, with 5 vertebrae; the *sacral* (pelvic) region, with 5 fused vertebrae; and the *coccygeal* region, also composed of fused vertebrae.

The *rib cage* is a bony “basket” formed by the *sternum* (breastbone), thoracic vertebrae, and, in mammals, 12 pairs of ribs. The rib cage protects the internal organs of the chest, including the heart and lungs. It also supports the chest wall, preventing it from collapsing as the diaphragm contracts with each breath. Each pair of ribs is attached dorsally to a separate vertebra. Of your 12 pairs of ribs, the first 7 are attached ventrally to the sternum; the next 3 are attached indirectly by cartilage; and the bottom 2, the “floating ribs,” have no attachments to the sternum.

The *pectoral girdle* consists of 2 collarbones, or *clavicles*, and 2 shoulder blades, or *scapulas*. The *pelvic girdle* consists of a pair of large bones, each composed of 3 fused hip bones. Whereas the pelvic girdle is securely fused to the vertebral column, the pectoral girdle is loosely and flexibly attached to it by muscles.

Each human limb consists of 30 bones and terminates in five *digits*, the fingers and toes. The more specialized appendages of other tetrapods may be characterized by four digits (as in the pig), three (the rhinoceros), two (the camel), or one (the horse).

A typical long bone amplifies the motion generated by muscles

The radius, one of the two bones of the forearm, is a typical long bone (**FIG. 40-6**). Its numerous muscle attachments are arranged in such a way that the bone rotates about its long axis and operates

Figure 40-5 The human skeletal system
Only a few of the 206 named bones are labeled here.

as a lever, amplifying the motion generated by the muscles. By themselves, muscles cannot shorten enough to produce large movements of the body parts to which they are attached.

Like other bones, the radius is covered by a connective tissue membrane, the *periosteum*, to which muscle tendons and ligaments attach. The periosteum can produce new layers of bone, thus increasing the bone's diameter. The main shaft of a long bone is its *diaphysis*, and each expanded end is an *epiphysis*. In children a disc of cartilage, the *metaphysis*, lies between the epiphyses and the diaphysis. Metaphyses are growth centers that disappear at maturity, becoming vague *epiphyseal lines*. Long bones have a central cavity that contains **bone marrow**. Yellow marrow consists mainly of a fatty connective tissue; the red marrow in certain bones produces blood cells.

The radius has a thin outer shell of **compact bone**, which is very dense and hard. Compact bone lies primarily near the surfaces of a bone, where it provides great strength. Recall from Chapter 39 that compact bone consists of interlocking spindle-shaped units called **osteons** (see Fig. 39-2). Within an osteon, **osteocytes** (bone cells) lie in small cavities called *lacunae* (sing.,

lacuna). The lacunae are arranged in concentric circles around central **Haversian canals**. Blood vessels that nourish the bone tissue pass through the Haversian canals. Osteocytes are connected by threadlike extensions of their cytoplasm that extend through narrow channels (called *canaliculi*).

Interior to the thin shell of compact bone is a filling of **spongy bone** that provides mechanical strength. Spongy bone consists of a network of thin strands of bone. Its spaces are filled with bone marrow.

Bones are remodeled throughout life

Bones are modeled during growth and remodeled continuously throughout life in response to physical stress and other changing demands. As muscles develop in response to physical activity, the bones to which they are attached thicken and become stronger. **Osteoblasts** are bone-building cells. They secrete the protein collagen, which forms the strong fibers of bone. The compound hydroxyapatite, composed mainly of calcium phosphate, is present in the interstitial fluid (tissue fluid). It automatically crystallizes around the collagen fibers to form the hard matrix of bone. As the matrix forms around the osteoblasts, they become isolated within the lacunae. The trapped osteoblasts are then called **osteocytes**.

Osteoclasts are large, multinucleated cells that resorb (break down) bone. The osteoclasts move about, secreting hydrogen ions that dissolve the crystals and enzymes that digest the collagen. Osteoclasts and osteoblasts are synergistic; together they shape bones. The remodeling process is an extensive process of breaking down and rebuilding bone. The adult human skeleton is completely replaced every 10 years!

In *osteoporosis*, the most common progressive and degenerative bone disease, bone is broken down more rapidly than it is rebuilt. In women, the decrease in estrogen after menopause accelerates bone resorption. Osteoporosis patients lose so much bone mass that their bones become fragile and fracture easily.

Joints are junctions between bones

Joints, or articulations, are junctions between two or more bones. Joints facilitate flexibility and movement. At the joint, the outer surface of each bone consists of *articular cartilage*.

Figure 40-6 A typical long bone

A long bone has a thin shell of compact bone and a filling of spongy bone that contains marrow.

One way to classify joints is according to the degree of movement they allow. The *sutures* between bones of the human skull are *immovable joints*. In a suture, bones are held together by a thin layer of dense fibrous connective tissue, which may be replaced by bone in the adult. *Slightly movable joints*, found between vertebrae, are made of cartilage. These joints help absorb shock.

Most joints are *freely movable joints*. Each is enclosed by a joint capsule of connective tissue and lined with a membrane that secretes a lubricant called *synovial fluid*. This viscous fluid reduces friction during movement and absorbs shock. The joint capsule is typically reinforced by **ligaments**, bands of fibrous connective tissue that connect bones and limit movement at the joint.

With time and use, joints wear down. In *osteoarthritis*, a group of common joint disorders, cartilage repair does not keep up with degeneration, and the articular cartilage wears out. Inflammation of the joint capsule may occur, and bone outgrowths, or spurs, may develop. In *rheumatoid arthritis*, an autoimmune disease, the synovial membrane thickens and becomes inflamed. Synovial fluid accumulates, causing pressure, pain, stiffness, and progressive deformity, leading to loss of function.

✓ CHECKPOINT 40.2

- **CONNECT** How do the septa in the annelid worm contribute to the effectiveness of its hydrostatic skeleton?
- What are some advantages of an exoskeleton? some disadvantages?
- What are the main bones in each division of the human skeleton?
- How do osteoblasts and osteoclasts remodel bone?

40.3 Muscle Contraction

🎯 LEARNING OBJECTIVES

- 7 Relate the structure of insect flight muscles to their function.
- 8 Describe the structure of skeletal muscles and their antagonistic actions.
- 9 List, in sequence, the events that take place during muscle contraction.
- 10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.
- 11 Compare the structures and functions of the three types of skeletal muscle fibers.
- 12 Describe factors that influence muscle contraction.

Most animals have the ability to move from place to place. Throughout most of the animal kingdom, a *muscular system* generates the mechanical forces and motion necessary for locomotion and for manipulation of objects. Muscle also powers many physiological actions necessary to maintain homeostasis. Many animals have digestive systems that push food along with peristaltic contractions and hearts that pump internal circulating fluids. Some animals also have blood vessels that maintain their pressure with gentle squeezing.

Animals with very simple body plans do not have muscle tissue, but all eukaryotic cells do contain the contractile protein **actin**. The major component of microfilaments (see Fig. 4-27), actin is important in many cell processes, including amoeboid movement and attachment of cells to surfaces. In most cells actin is functionally associated with the contractile protein **myosin**. Actin and myosin are most highly organized in muscle fibers.

Invertebrate muscle varies among groups

Earlier in this chapter, we discussed the contractile cells of the hydrostatic skeleton of *Hydra* and other cnidarians. In most other animal groups, muscle is a specialized tissue organized into definite layers, or straplike bands. Some invertebrate phyla have skeletal and smooth muscle. Bivalve mollusks, such as clams, have two sets of muscles for opening and closing the shell. Their specialized smooth muscle, which is capable of slow, sustained contraction at low energy cost, keeps the two shells tightly closed for long periods, even weeks at a time.

Striated muscle, which contracts rapidly, is used to swim and to shut the shell quickly when the mollusk is threatened. Arthropod muscles are striated, even in the walls of the digestive tract.

Insects were the first animals in which flight evolved, an adaptation that has contributed to their impressive biological success (see Chapter 31). Just how insects fly has been an aerodynamic mystery, and scientists are working to understand their remarkable ability to maneuver. Insect flight muscles contract more rapidly than any other known muscle, up to 1000 contractions per second! Not surprisingly, insect flight muscles in action have the highest known metabolic rate of any muscle tissue.

As you might imagine, insect flight muscles are structurally well adapted to their function. They contain more mitochondria than any other known variety of muscle. Their mitochondria have more cristae (folds of their inner membranes) and can consume oxygen twice as fast as mammalian mitochondria. Insect muscles are also elaborately infiltrated with *tracheae*, tiny air-filled tubes that carry oxygen directly to each muscle fiber.

Many insects must warm up before they fly because an increase in body temperature increases the rate of ATP synthesis. Butterflies and some other insects bask in the sun before they fly. Honeybees “shiver” their muscles to increase body temperature.

Vertebrate skeletal muscles act antagonistically to one another

Skeletal muscles produce movements by pulling on **tendons**, tough cords of connective tissue that anchor muscles to bone. Tendons then pull on bones. Skeletal muscles, or their tendons, pass across a joint and are attached to the bones on each side of the joint. When the muscle contracts, it pulls one bone toward or away from the bone with which it articulates.

Because muscles can only contract, they can only pull; they cannot push. Muscles act **antagonistically** to one another, which means that the movement produced by one can be reversed by another. For example, contraction of the biceps muscle flexes (bends) your arm, whereas contraction of the triceps muscle extends it (FIG. 40-7).

The muscle that contracts to produce a particular action is known as the *agonist*. The muscle that produces the opposite movement is the *antagonist*. When the agonist is contracting, the antagonist is relaxed. Generally, movements are accomplished by groups of muscles working together, so several agonists and several antagonists may take part in any action. Note that muscles that are agonists in one movement may serve as antagonists in another. Some of the superficial skeletal muscles of the human body are shown in FIGURE 40-8.

A vertebrate muscle may consist of thousands of muscle fibers

Skeletal muscle is the most abundant tissue in the vertebrate body. Its elongated cells, called **muscle fibers**, are organized in bundles wrapped by connective tissue.

The biceps in your arm, for example, consists of thousands of individual muscle fibers and their connective tissue coverings.

Each striated muscle fiber is a long, cylindrical cell with many nuclei (FIG. 40-9). The plasma membrane, known as the **sarcolemma** in a muscle fiber, has multiple inward extensions that form a set of **T tubules** (transverse tubules). The cytoplasm of a muscle fiber is called *sarcoplasm*, and the endoplasmic reticulum is called the **sarcoplasmic reticulum**.

Myofibrils are threadlike structures that run lengthwise through the muscle fiber. They consist of even smaller structures called **filaments**. There are two types of filaments: myosin and actin filaments. **Myosin filaments** are thick, consisting mainly of the protein myosin. The thin **actin filaments** consist mostly of the protein actin; they also contain the proteins **tropomyosin** and **troponin**, which regulate the actin filament's interaction with myosin filaments.

Myosin and actin filaments are organized into repeating units called **sarcomeres**, the basic units of muscle contraction. Hundreds of sarcomeres connected end to end make up a myofibril. Sarcomeres are joined at their ends by a thin band of interweaving filaments called the *Z line*. Each sarcomere consists of overlapping myosin and actin filaments. The filaments overlap lengthwise in the muscle fibers, producing the pattern of transverse bands or striations characteristic of striated muscle (FIG. 40-10 on page 852; also see Fig. 40-9).

The bands in striated muscle are designated by the letters A, H, and I. The *I band* consists of parts of actin filaments of two

(a) **Flexion.** When the biceps muscle contracts, the arm flexes (bends).

(b) **Extension.** When the triceps muscle contracts, the arm extends.

Figure 40-7 Muscle action

The biceps and triceps muscles function antagonistically.

Figure 40-8 Some superficial muscles of the human body
The labels in boldface are bones.

adjacent sarcomeres. The *A band* is the wide, dark region that includes overlapping myosin and actin filaments. Within the *A band* is a narrow, light area, the *H zone*, made up exclusively of myosin filaments; the actin filaments do not extend into this region. A system of proteins holds each stack of myosin filaments together. These proteins are visible as a thin line, the *M line*, that extends down the center of the *H zone* within the *A band*.

Contraction occurs when actin and myosin filaments move past one another

Muscle contraction occurs when the muscle fibers, and thus the sarcomeres, shorten. This explanation of muscle contraction, known as the **sliding filament model**, was developed

in the 1950s by two British biologists, Hugh Huxley and Andrew Huxley. (The Huxleys were not related. They worked separately, and they independently came to the same general conclusions at about the same time.) Thanks to the Huxleys, we now understand that the muscle shortens as the actin and myosin filaments use a ratcheting mechanism to move past one another, increasing their overlap. You might think of an extension ladder. The overall ladder length changes as the ends get closer or farther apart, but the length of each ladder section stays the same. The *I band* and *H zone* decrease in length, but neither the actin nor myosin filaments themselves shorten.

Motor neurons transmit messages from the brain or spinal cord to muscle fibers. When a motor neuron transmits a

Figure 40-9 Muscle structure

A skeletal muscle fiber contains threadlike myofibrils that consist of actin and myosin filaments. These filaments are organized into repeating units called sarcomeres. The regular pattern of overlapping filaments gives skeletal and cardiac muscle their striated appearance.

Key Point

A muscle contracts when actin and myosin filaments move past one another. The length of each filament remains the same.

Figure 40-10 The sliding filament model of muscle contraction

Myosin and actin filaments are organized into repeating units called sarcomeres. As the sarcomeres become shorter, the muscle fiber shortens, but the size of the filaments does not change. (The I band consists of actin filaments of two adjacent sarcomeres.)

PREDICT How would the volume of myofibrils in a muscle fiber affect the force that the muscle can generate?

message, it releases the neurotransmitter **acetylcholine** into the **synaptic cleft**, a small space between the motor neuron and each muscle fiber. Acetylcholine binds with receptors on each muscle fiber, causing **depolarization**, a change in the distribution of electric charge across its sarcolemma. Depolarization can generate an **action potential**, an electrical signal that travels along the membrane of the muscle fiber (or neuron).

In a muscle fiber, an action potential is a wave of depolarization that travels along the sarcolemma and into the system of T-tubule membranes. Depolarization of the T tubules opens calcium channels in the sarcoplasmic reticulum, and stored calcium ions are released into the myofibrils. Calcium ions bind to the protein troponin on the actin filaments, which changes the shape of the troponin. This change results in the troponin pushing tropomyosin away from the *active sites* on the actin filament (**FIG. 40-11**). These active sites, also called *myosin-binding sites*, are now exposed.

One end of each myosin molecule is folded into two globular structures called *heads*. The rounded heads of the myosin molecules extend away from the body of the myosin filament. Each myosin molecule also has a long tail that joins other myosin tails to form the body of the thick filament. ATP is bound to the myosin when the muscle fiber is at rest (not contracting). Myosin is an adenosine triphosphatase (ATPase), an enzyme that splits ATP to form ADP and inorganic phosphate (P_i). Myosin converts the chemical energy of ATP into the mechanical energy of sliding filaments.

According to the current model of muscle contraction, when ATP is split, the ADP and P_i initially remain attached to the myosin head. The myosin head (with ADP and P_i still bound to it) is in an energized state; it is “cocked.” The myosin head binds to an exposed active site on the actin filament, forming a **cross bridge** linking the myosin and actin filaments. The inorganic phosphate is then released, which triggers a conformational change in the myosin head. The myosin head bends about 45 degrees, in a flexing motion. This movement, the *power stroke*, pulls the actin filament closer to the center of the sarcomere. During the power stroke, the ADP is released.

A new ATP must bind to the myosin head before the myosin can detach from the actin. If sufficient calcium ions are present, the cycle begins anew. Energized once again, myosin heads contact a second set of active sites on the actin filament. This next set is farther down the filament, closer to the end of the sarcomere. The process repeats with a third set of active sites, and so on. This series of stepping motions pulls the actin filaments toward the center of the sarcomere.

Each time the myosin heads attach, move 45 degrees, detach, and then re-attach farther along the actin filament, the muscle shortens. One way to visualize this process is to imagine the myosin heads engaging “hand over hand” with the actin filaments. When many sarcomeres contract simultaneously, they contract the muscle as a whole. The sequence of events in muscle contraction can be summarized as follows:

1. A motor neuron releases acetylcholine, which binds with receptors on the muscle fiber; binding causes depolarization and generation of an action potential.

2. The action potential spreads through T tubules, triggering Ca^{2+} release from the sarcoplasmic reticulum.
3. Ca^{2+} bind to troponin, causing troponin to change shape, which exposes the active sites on the actin filaments.
4. ATP (attached to myosin) is split, and the energized myosin head is cocked; it binds to the active site on the actin filament, forming a cross bridge.
5. The release of P_i from the myosin head triggers the power stroke.
6. During the power stroke, the myosin head pulls the actin filament toward the center of the sarcomere, shortening the muscle; ADP is released.
7. The myosin head binds a new ATP and detaches from actin. If the concentration of Ca^{2+} is high enough, the cycle repeats from step 3.

ATP powers contraction through repeated cycles of cross bridge formation followed by myosin heads pulling actin filaments toward the center of the sarcomere.

When impulses from the motor neuron cease, the enzyme acetylcholinesterase in the synaptic cleft inactivates acetylcholine. Muscle fibers return to their resting state. Calcium ions are pumped back into the sarcoplasmic reticulum by active transport, a process that requires ATP. Calcium removal is the key step in muscle relaxation. Without Ca^{2+} , tropomyosin once again covers active sites on the actin filaments. The actin filaments move back to their original position, and the muscle relaxes. This entire series of events happens in milliseconds.

ATP powers muscle contraction

Muscle cells often perform strenuously and need large amounts of energy. As noted, the immediate source of energy for muscle contraction is ATP. Energy stored in ATP molecules powers attachment of the myosin heads to the actin filaments, bending of the cross bridges, and release of the myosin heads. Note that energy is needed not only for the pull exerted by the cross bridges, but also for their release from each active site.

Rigor mortis, the temporary but very marked muscle stiffening that occurs after death, results from ATP depletion. When death occurs, cellular respiration ceases, and ATP is used up. However, at the time of death, many muscle fibers are in the process of contraction, and cross bridges have formed. Because ATP is essential for release of the myosin heads, cross bridges remain intact. Rigor mortis does not persist indefinitely because the entire contractile apparatus of the muscles eventually decomposes, restoring pliability. The phenomenon is temperature dependent, so given the prevailing temperature, a medical examiner can estimate the time of death of a cadaver from its degree of rigor mortis.

ATP molecules can provide energy for only a few seconds of strenuous activity. Muscle fibers have a backup energy storage compound, **creatine phosphate**, that can be stockpiled. The energy stored in creatine phosphate is transferred to ATP as needed, but during vigorous exercise the supply of creatine

The energy of ATP powers muscle contraction. During the power stroke, myosin heads move actin filaments toward the center of the sarcomere, which shortens the muscle.

Figure 40-11 Muscle contraction: model of actin and myosin interactions

Contraction results when actin filaments move toward the center of individual sarcomeres of a myofibril. After step 7, the cycle repeats from step 3 if calcium ions are available. In the absence of calcium ions, the muscle relaxes.

PREDICT How would muscle contraction be affected if the body stopped producing acetylcholine?

phosphate is quickly depleted. Muscle cells must replenish their supplies of these energy-rich compounds.

Fortunately, there is yet another backup energy storage compound. Muscle fibers store chemical energy in **glycogen**, a large polysaccharide formed from hundreds of glucose molecules. Glycogen can be degraded, yielding glucose, which is then degraded in cellular respiration (see Chapters 3 and 8). When sufficient oxygen is available, enough energy is captured from glucose to produce needed quantities of ATP and creatine phosphate.

During a burst of strenuous exercise, the circulatory system cannot deliver enough oxygen to keep up with the demand of the rapidly metabolizing muscle fibers. The result is an **oxygen debt**. Under these conditions, muscle fibers break down fuel molecules anaerobically (without oxygen) for short periods. Lactic acid fermentation is a method of generating ATP anaerobically, but not in great quantity (see Fig. 8-14c). ATP depletion results in weaker contractions and muscle fatigue. Accumulation of the waste product **lactic acid** also contributes to muscle fatigue. Well-conditioned athletes develop the ability to tolerate the high levels of lactic acid generated during high-performance activity. The period of rapid breathing that generally follows strenuous exercise pays back the oxygen debt by consuming lactic acid.

The type of muscle fibers determines strength and endurance

Three major types of skeletal muscle fibers have been identified in vertebrates: slow-oxidative, fast-oxidative, and fast-glycolytic fibers (**TABLE 40-1**). **Slow-oxidative fibers** are well adapted for endurance activities such as swimming and running long distances. These fibers also help maintain posture. They contract slowly and fatigue slowly. Slow-oxidative fibers require a steady supply of oxygen. They derive most of their energy from aerobic respiration and are rich in mitochondria and capillaries. Slow-oxidative fibers are rich in **myoglobin**, a red pigment similar to hemoglobin, which stores oxygen in red blood cells. Myoglobin enhances rapid diffusion of oxygen from blood into muscles during strenuous muscle exertion. Because of their myoglobin, slow-oxidative fibers are red and are sometimes called red fibers.

Fast-oxidative fibers contract rapidly and have an *intermediate* rate of fatigue. Like slow-oxidative fibers, they

are rich in mitochondria and obtain most of their ATP from aerobic respiration. They also have a high myoglobin content and a red color.

Fast-glycolytic fibers generate a great deal of power and carry out rapid movements but can sustain that activity for only a short time. They are important in activities such as sprinting and weight lifting. Fast-glycolytic fibers contract rapidly, have few mitochondria, and obtain most of their energy from glycolysis. When their glycogen supply is depleted, they fatigue rapidly. These fibers have a low myoglobin content and are white. (They are sometimes referred to as white fibers.) People who are sedentary have more fast-glycolytic fibers than do physically fit individuals. With physical training, these fibers change to fast-oxidative fibers.

Entire muscles may be specialized for quick or slow responses. In chickens, for instance, the white breast muscles are efficient for quick responses, perhaps because a short flight is an escape mechanism for chickens. However, they walk about on the ground all day; the dark (red) meat of the leg and thigh is muscle specialized for more sustained activity. Birds that fly have red breast muscles specialized to support sustained activity.

In humans most muscles have a mixture of different types of fibers. The proportions of the types of fibers vary among individuals and from muscle to muscle in the same person. Aerobic exercise, such as jogging or bicycling, increases endurance. *Aerobic training* increases capillary density, the number of mitochondria, and the myoglobin content of muscle fibers. In *strength training*—for example, weight lifting—specific muscles are repeatedly contracted under heavy loads. This action increases the number of filaments in the muscle fibers, which increases the size of the muscle.

Several factors influence the strength of muscle contraction

In addition to the types of muscle fibers making up the muscle, contraction of a whole muscle depends on the number of muscle fibers contracting, the tension developed by each fiber, frequency of stimulation, condition of the muscle (e.g., whether or not it is fatigued), and the load on the muscle. As more muscle fibers contract, the tension in the muscle increases.

Table 40-1 Characteristics of Skeletal Muscle Fibers

Characteristics	Slow-Oxidative Fibers	Fast-Oxidative Fibers	Fast-Glycolytic Fibers
Contraction speed	Slow	Fast	Fast
Rate of fatigue	Slow	Intermediate	Fast
Major pathway for ATP synthesis	Aerobic respiration	Aerobic respiration	Glycolysis
Mitochondria	Many	Many	Few
Intensity of contraction	Low	Intermediate	High
Myoglobin content	High	High	Low
Color of fiber	Red	Red	White

In a **motor unit**, a motor neuron is functionally connected with an average of about 150 muscle fibers (**FIG. 40-12**). However, some motor units have fewer than a dozen motor neurons, and others have several hundred. Each junction of a motor neuron with a muscle fiber is called a *neuromuscular junction*. Messages from the brain or spinal cord activate motor units. The more motor units *recruited*, the stronger the contractions.

Figure 40-12 A motor unit

A motor unit consists of a motor neuron and the muscle fibers that it innervates.

An important factor affecting the tension of contracting muscle fibers is the frequency of stimulation. In response to a single, brief electrical stimulus, skeletal muscle contracts with a single, quick contraction called a *simple twitch*. When a second stimulus is received before the first contraction is complete, the two twitches may add together, a process called **summation** (**FIG. 40-13**). Typically, skeletal muscle receives a series of separate stimuli timed very closely together. Summation results in a smooth, sustained contraction called *tetanus*. The identity and number of our muscle fibers that are tetanically contracting help determine whether we can play the piano, draw a picture, rock a baby, drive a car, or run a mile.

When you lift a heavy object, you place a load on the muscles affected. As the weight of the load increases, the muscles contract more strongly (within limits).

Even when you are not moving, your muscles are in a state of partial contraction known as **muscle tone**. At any given moment, some muscle fibers are contracted, stimulated by messages from motor neurons. Muscle tone is an unconscious process that keeps muscles prepared for action. When the motor nerve to a muscle is cut, the muscle becomes limp (completely relaxed, or flaccid) and eventually atrophies (decreases in size).

Smooth muscle and cardiac muscle are involuntary

The three types of vertebrate muscle—skeletal, smooth, and cardiac—are compared in Table 39-3. All three types of muscle have thin actin filaments that move along thick myosin filaments in response to an increase in calcium ion concentration. All three muscle types use ATP to power contraction. However, each type of muscle is specialized for particular types of responses. Neither smooth muscle nor cardiac muscle is under voluntary control.

Smooth muscle is not attached to bones but instead forms tubes that squeeze like the muscle tissue in the body wall of the earthworm. Smooth muscle contracts in response to simple stretching, and its contraction tends to be sustained. It is well adapted to performing such tasks as regulating blood pressure by sustained contraction of the walls of the arterioles. Although smooth muscle contracts slowly, it shortens much more than striated muscle does; it squeezes impressively.

Smooth muscle is not striated because its actin and myosin filaments are not organized into myofibrils or into sarcomeres. The fibers of smooth muscle tissue function as a unit because they are connected by *gap junctions* (see Fig. 5-23c). Gap junctions permit electrical signals to pass rapidly from fiber to fiber. Although smooth muscle contraction is similar to skeletal muscle contraction (occurring by a sliding filament mechanism), the cross bridges in smooth muscle remain in the attached state longer. For this reason, less ATP is required to maintain a high level of force in smooth muscle than in skeletal muscle.

Cardiac muscle contracts and relaxes in alternating rhythm, propelling blood with each contraction. Sustained contraction of cardiac muscle would be disastrous! Cardiac

(a) When a muscle fiber is allowed to completely relax and is then stimulated a second time, the second twitch is the same magnitude as the first twitch.

(b) When a muscle fiber is stimulated a second time before it has completely relaxed, the second twitch is added on to the first twitch. The result is summation.

(c) A volley of rapid stimuli does not allow the muscle fiber to relax between stimuli. The result is a sustained contraction called tetanus.

Figure 40-13 Summation and tetanus

muscle fibers are electrically coupled by junctions called **intercalated discs**. Gap junctions within the intercalated discs allow action potentials to spread rapidly from one cardiac fiber to another.

Each heartbeat is initiated by a *pacemaker*, a mass of specialized cardiac muscle. A conduction system transmits the signal throughout the cardiac muscle. The cardiac fibers within the atria contract as a functional unit, and the cardiac fibers within the ventricles also function as a functional unit. The heart beats in a regular rhythm independent of a nerve supply. However, the heart rate is regulated, according to the needs of the body, by neurons in the cardiac centers in the medulla of the brain (discussed in Chapter 44).

CHECKPOINT 40.3

- **VISUALIZE** Sketch a longitudinal section of a sarcomere in a relaxed state. Label the Z lines, thin filaments, and thick filaments. Which filaments are actin? myosin?
- What is the sequence of events that occur when a muscle fiber contracts (begin with release of acetylcholine and include cross-bridge action)?
- Compare and contrast the functions of ATP, creatine phosphate, and glycogen in muscle contraction.
- Compare skeletal, smooth, and cardiac muscle.

Summary: Focus on Learning Objectives

40.1 Epithelial Coverings (page 843)

1 Compare the functions of the epithelial coverings of invertebrates and vertebrates.

- **Epithelial tissue** protects underlying tissues and may be specialized for sensory or respiratory functions. The outer epithelium may be specialized to secrete antibacterial or poisonous substances.
- In many invertebrates, the outer epithelium is specialized to secrete a protective **cuticle**, or a shell.
- The **integumentary system** of vertebrates includes the skin and structures that develop from it. Mammalian skin includes hair, claws or nails, sweat glands, oil glands, and sensory receptors.

2 Relate the structure of vertebrate skin to its functions.

- The feathers of birds and the hair of mammals form an insulating layer that helps maintain a constant body temperature. Mammalian skin protects the body from the wear and tear that occurs as it interacts with the outer environment. **Stratum corneum**, the most superficial layer of the **epidermis**, consists of dead cells filled with **keratin**, a protein that gives mechanical strength to the skin and reduces water loss. Cells in **stratum basale**, the deepest layer of the epidermis, divide and are pushed upward toward the skin surface. These cells mature, produce keratin, and eventually die and slough off.

- The **dermis** consists of dense, fibrous connective tissue. In birds and mammals, the dermis rests on a layer of *subcutaneous tissue* composed largely of insulating fat.

40.2 Skeletal Systems (page 844)

3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.

- The **skeletal system** supports and protects the body and transmits mechanical forces generated by muscles. Many soft-bodied invertebrates have a **hydrostatic skeleton**; fluid in a closed body compartment is used to transmit forces generated by contractile cells or muscle.
- **Exoskeletons** are characteristic of mollusks and arthropods. The arthropod skeleton, composed partly of **chitin**, is jointed for flexibility and adapted for many lifestyles. This nonliving skeleton does not grow, making it necessary for arthropods to undergo **ecdysis (molting)** periodically.
- The **endoskeletons** of echinoderms and chordates consist of living tissue and therefore can grow.

4 Describe the main divisions of the vertebrate skeleton and identify the bones that make up each division.

- The vertebrate skeleton consists of an *axial skeleton* and an *appendicular skeleton*. The axial skeleton consists of the *skull*, the **vertebral column**, the *rib cage*, and the *sternum*. The appendicular skeleton consists of the bones of the limbs, the *pectoral girdle*, and the *pelvic girdle*.

5 Describe (or draw and label) the structure of a typical long bone and contrast the roles of osteoblasts and osteoclasts in bone remodeling.

- A typical long bone consists of a thin outer shell of **compact bone** surrounding the inner **spongy bone** and a central cavity that contains **bone marrow**.
- **Osteoblasts**, cells that produce bone, and **osteoclasts**, cells that break down bone, work together to shape and remodel bone.

6 Compare the main types of vertebrate joints.

- **Joints** are junctions of two or more bones. **Ligaments** are connective tissue bands that connect bones and limit movement at the joint.
- The sutures of the skull are *immovable joints*. Joints between vertebrae are *slightly movable joints*. A *freely movable joint* is enclosed by a joint capsule lined with a membrane that secretes *synovial fluid*.

40.3 Muscle Contraction (page 848)

7 Relate the structure of insect flight muscles to their function.

- Large numbers of mitochondria and tracheae (air tubes) present in insect flight muscles support the high metabolic rate required for flight.

8 Describe the structure of skeletal muscles and their antagonistic actions.

- Vertebrates, as well as most invertebrates, have a *muscular system*. As muscle tissue contracts (shortens), it moves body parts by pulling on them.
- Vertebrate skeletal muscles pull on **tendons**, connective tissue cords that attach muscles to bones. When a muscle contracts, it pulls a bone toward or away from the bone with which it articulates.
- Skeletal muscles act *antagonistically* to one another. The muscle that produces a particular action is the *agonist*; the *antagonist* produces the opposite movement.
- A skeletal muscle such as the biceps is an organ made up of hundreds of **muscle fibers**. Each fiber consists of threadlike **myofibrils** composed of smaller **filaments**. The striations of skeletal muscle fibers reflect the overlapping of their **actin filaments** and **myosin filaments**. A **sarcomere** is a contractile unit of actin (thin) and myosin (thick) filaments.

9 List, in sequence, the events that take place during muscle contraction.

- **Acetylcholine** released by a motor neuron binds with receptors on the surface of a muscle fiber. This may cause **depolarization** of the sarcolemma and transmission of an **action potential**. The action potential spreads through the **T tubules**, releasing calcium ions from the **sarcoplasmic reticulum**.
- Calcium ions bind to **troponin** in the actin filaments, causing the troponin to change shape. Troponin pushes **tropomyosin** away from the binding sites on the actin filaments.
- ATP binds to myosin; ATP is split, putting the myosin head in a high-energy state (it is "cocked"). Energized myosin heads attach to the exposed binding sites on the actin filaments, forming **cross bridges** that link the myosin and actin filaments.
- After myosin attaches to the actin filament, the cross bridge flexes as phosphate is released. This power stroke pulls the actin filament toward the center of the sarcomere. ADP is released during the power stroke.
- The myosin head binds a new ATP, which lets the myosin head detach from the actin. As long as the calcium ion concentration remains elevated, the new ATP is split, and the sequence repeats. The myosin re-attaches to new active sites so that the filaments are pulled past one another, and the muscle continues to shorten.

10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.

- ATP is the immediate source of energy for muscle contraction. ATP hydrolysis provides the energy to "cock" the myosin. Muscle tissue has an intermediate energy storage compound, **creatine phosphate**. **Glycogen** is the fuel stored in muscle fibers.

11 Compare the structures and functions of the three types of skeletal muscle fibers.

- **Slow-oxidative fibers** are specialized for endurance activities. They contract slowly, fatigue slowly, are rich in mitochondria, and obtain most of their ATP from aerobic respiration.

These fibers have a red color because they have a high content of **myoglobin**, a red pigment that stores oxygen.

- **Fast-oxidative fibers** are specialized for rapid response. They contract quickly and have an intermediate rate of fatigue. Like slow-oxidative fibers, they are rich in mitochondria, obtain most of their ATP from aerobic respiration, have a high myoglobin content, and have a red color.
- **Fast-glycolytic fibers** generate a great deal of power for a brief period. These white fibers contract rapidly, fatigue quickly, have few mitochondria, and use glycolysis as a major pathway for ATP synthesis.

12 Describe factors that influence muscle contraction.

- Contraction of a whole muscle depends on several factors, including the number of muscle fibers contracting, tension developed by each fiber, frequency of stimulation, condition of the muscle, and load on the muscle.
- A **motor unit** consists of all the skeletal muscle fibers stimulated by a single motor neuron. Messages from the brain or spinal cord activate motor units. The more motor units *recruited*, the stronger the contractions.

- When activated by a brief electrical stimulus, skeletal muscle responds with a *simple twitch*. When a second stimulus is received before the first contraction is complete, the two twitches can add together, a process called **summation**. Typically, skeletal muscle is stimulated by a series of separate stimuli timed close together and responds with a smooth, sustained contraction called *tetanus*.
- **Muscle tone** is the state of partial contraction characteristic of muscles.
- In contrast to skeletal muscle, **smooth muscle** and **cardiac muscle** are not under voluntary control. The sustained contractions of smooth muscle are adapted for tasks such as regulating blood pressure by contraction of arteriole walls. Cardiac muscle contracts and relaxes in an alternating rhythm, pumping blood with each contraction. **Intercalated discs** are junctions that electrically couple cardiac muscle fibers. These discs allow action potentials to spread rapidly from one cardiac muscle fiber to another.

Test Your Understanding

Know and Comprehend

1. An endoskeleton (a) is typically composed of dead tissue (b) is characterized by fluid in a closed compartment (c) is found mainly in echinoderms and vertebrates (d) is typical of echinoderms and arthropods (e) requires the animal to molt
2. Which of the following is part of the vertebrate appendicular skeleton? (a) skull (b) vertebral column (c) pelvic girdle (d) rib cage (e) sternum
3. An energy storage compound that can be stockpiled in muscle cells for short-term use is (a) myoglobin (b) ADP (c) troponin (d) myosin (e) creatine phosphate
4. Calcium ions are released from the sarcoplasmic reticulum. What happens next? (a) acetylcholine is released (b) active sites on the actin filaments are exposed (c) filaments move past one another, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
5. Myosin binds to actin, forming a cross bridge. What happens next? (a) acetylcholine is released (b) calcium ions stimulate exposure of active sites (c) myosin filaments move past one another, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
6. When skeletal muscle is stimulated by a series of closely timed separate stimuli, (a) white fibers respond (b) a simple twitch occurs (c) the muscle responds with a smooth, sustained contraction called tetanus (d) red fibers respond (e) summation is inhibited

Apply and Analyze

7. Insect flight muscles have a very high metabolic rate. In what way is this characteristic adaptive?

8. **VISUALIZE** Label the diagram.

Evaluate and Synthesize

9. **INTERPRET DATA** Examine Figure 40-13. Based on the summation of two stimuli shown in that graph, draw a curve showing summation when the muscle fiber is stimulated three times.
10. Skeletal muscles are able to shift functions, sometimes acting as an agonist and other times acting as an antagonist. How is this ability to shift functions advantageous?
11. **CONNECT** What is the functional relationship between skeletal and muscle tissues? How can muscle damage affect skeletal tissue?
12. **EVOLUTION LINK** Very different skeletal systems have evolved in arthropods and vertebrates. What are some benefits and some disadvantages of each type of skeleton? In what way is the insect skeleton an adaptation to the insect lifestyle?
13. **EVOLUTION LINK** What does human muscle contraction have in common with cellular movement in single-cell organisms?
14. **SCIENCE, TECHNOLOGY, AND SOCIETY** Explore the relationships between society's need for joint replacements and the interconnections of science and technology with this need.

41 Neural Signaling

KEY CONCEPTS

- 41.1** Neural signaling involves reception, transmission, integration, and action by effectors.
- 41.2** Neurons are specialized to receive stimuli and transmit signals; glial cells support, protect, and nourish neurons, and they can modify neural signals.
- 41.3** The resting potential of a neuron is maintained by ion channels and ion pumps. Depolarization of the neuron plasma membrane to threshold level generates action potentials, the electrical signals transmitted by axons.
- 41.4** Most neurons signal other cells by releasing neurotransmitters at chemical synapses.
- 41.5** During integration, incoming neural signals are summed; temporal and spatial summation can bring a neuron to threshold level.
- 41.6** Neurons are organized in specific pathways called neural circuits, which, in turn, are organized to form neural networks.

PHOTO: Some specialized cells in the central nervous system. This immunofluorescent light micrograph of mammalian spinal cord tissue shows astrocytes (*green*) and neurons (the smaller cells stained *pink*). Astrocytes are glial cells, regulatory cells thought to be important in learning and memory. The smaller *blue* dots are the nuclei of other types of glial cells. Nancy Kederasha/UCLA/Getty Images

An animal's ability to survive and to maintain homeostasis depends largely on how effectively it detects and responds to *stimuli*, the changes that take place in its environment. Most animals have a *nervous system* that takes in information, transmits it to the spinal cord and brain where it is integrated, and then responds. The nervous system is composed mainly of two specialized types of cells: *neurons* and *glial cells* (see photograph). Just how animals respond to stimuli depends on how their neurons are organized and connected to one another. A single neuron in the vertebrate brain may be functionally connected to thousands of other neurons.

The nervous system is the principal regulatory system in animals. Regulation requires communication, and the nervous system transmits information to and from all parts of the body. Neurobiology is one of the most exciting areas of biological research. Active areas of research include *neurotransmitters*, the chemical messengers used by neurons to signal other neurons, and the *receptors* that bind with the neurotransmitters.

Neurogenesis, the production of new neurons, has been a very interesting focus of research. One of the most time-honored views about the nervous system was that the brain of mammals could not generate new neurons after birth. Nobel laureate Santiago Ramon y Cajal promoted this concept at the beginning of the 20th century, and the idea that we are born with all the brain cells we will ever have was widely held for almost a century. Another enduring idea was that glial cells, the most common cells in the brain, simply provide support services for neurons. As we discuss in this chapter, researchers have demonstrated that both of these hypotheses are false.

In this chapter we focus on how information is communicated by neurons and glial cells. In Chapter 42 we discuss nervous systems, and in Chapter 43 we explore sensory reception.

41.1 Neural Signaling: An Overview

LEARNING OBJECTIVE

- 1 Describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors that brings about the actual response.

Thousands of stimuli constantly bombard an animal. Survival depends on identifying and evaluating these stimuli, and then responding effectively. Information about each stimulus must be transmitted *to* the nervous system, and then information *from* the nervous system must be transmitted to muscles and glands. Animals respond to changes in temperature, sound, light, odors, and movement that may indicate the presence of a predator or of prey. Internal signals, such as hunger, pain, fluctuations in blood pressure, or changes in blood glucose concentration, also demand responses. In most animals responses to stimuli depend on **neural signaling**, the transmission of information by **neurons**, conducting cells of the nervous system. Neural signaling typically involves four processes: reception, transmission, integration, and the action by effectors (muscles or glands) that brings about the actual response.

Reception, the process of detecting a stimulus, is the job of neurons and of specialized *sensory receptors* such as those in the skin, eyes, and ears (FIG. 41-1). **Neural transmission** is the process of sending messages along a neuron, from one neuron to another, or from a neuron to a muscle or gland. In vertebrates a neural message is transmitted from a receptor to the **central nervous system (CNS)**, which consists of the brain and spinal cord. Neurons that transmit information to the CNS are called **afferent neurons** (meaning “to carry toward”); they are also called **sensory neurons**.

Afferent neurons generally transmit information to **interneurons**, also known as association neurons, in the CNS. Most neurons, perhaps 99% of them, are interneurons. Their function is to *integrate* input and output. **Integration** involves sorting and interpreting incoming sensory information and determining the appropriate response.

Efferent neurons (meaning “to carry away”) transmit neural messages from the CNS to **effectors** (muscles and glands). Efferent neurons that signal skeletal muscle are called **motor neurons**. The *action by effectors* brings about the actual **response** to the stimulus. Sensory receptors and afferent and efferent neurons are part of the **peripheral nervous system (PNS)**. In summary, information flows through the nervous system in the following sequence:

reception by sensory receptor → transmission by afferent neuron
→ integration by interneurons in CNS → transmission by efferent neuron → action by effectors → actual response

CHECKPOINT 41.1

- **CONNECT** Imagine that you are swimming and suddenly spot a shark fin moving in your direction.

Figure 41-1 Response to a stimulus

Whether a stimulus originates in the outside world or inside the body, information must be received, transmitted to the central nervous system, integrated, and then transmitted to effectors (muscles and glands) that carry out some action, the actual response.

What sequence of processes must take place within your nervous system before you can make your escape?

- What happens after neural signals are integrated in the CNS?

41.2 Neurons and Glial Cells

LEARNING OBJECTIVES

- 2 Draw and label a typical neuron and give the function of each of its parts.
- 3 Identify the main types of glial cells and describe the functions of each.

Neurons and glial cells are unique to the nervous system. Neurons are specialized to receive and send information. Glial cells support and protect neurons and carry out many regulatory functions.

Neurons receive stimuli and transmit neural signals

The neuron is highly specialized to receive and transmit information. Neurons produce and transmit electrical signals called *nerve impulses*, or *action potentials*. The neuron is distinguished from other cells by its long *processes* (cytoplasmic extensions). Examine the structure of a common type of neuron, the multipolar neuron shown in **FIGURE 41-2**.

The largest portion of the neuron, the **cell body**, contains the bulk of the cytoplasm, the nucleus, and most of the other organelles. Typically, two types of processes project from the cell body of a multipolar neuron. Numerous *dendrites* extend from one end, and a long, single *axon* projects from the opposite end. **Dendrites** are typically short, highly branched processes specialized to receive stimuli and send signals to the cell body. The cell body integrates incoming signals.

Although microscopic in diameter, an **axon** may be 1 m (more than 1 yd) or more in length and may divide, forming branches called *axon collaterals*. The axon conducts nerve impulses away from the cell body to another neuron or to a muscle

or gland. At its end the axon divides, forming many *terminal branches* that end in *synaptic terminals*, also called *axon terminals*. The synaptic terminals release **neurotransmitters**, chemicals that transmit signals from one neuron to another or from a neuron to an effector. The junction between a synaptic terminal and another neuron (or effector) is called a **synapse**. Typically, a small space exists between these two neurons. Neurons communicate with one another at synapses.

In vertebrates the axons of many neurons outside the CNS are surrounded by a series of **Schwann cells**. The plasma membranes of these glial cells contain *myelin*, a white, fatty material. Schwann cells wrap their plasma membranes around the axon, forming an insulating covering called the **myelin sheath**. Gaps in the myelin sheath, called **nodes of Ranvier**, occur between successive Schwann cells. At these points the axon is not insulated with myelin. Axons more than 2 μm in diameter have myelin sheaths and are described as *myelinated*. Those of smaller diameter are generally *unmyelinated*. (The discussion in this chapter refers to both types of neurons unless otherwise stated.)

Certain regions of the CNS produce new neurons

At the beginning of this chapter, we described Cajal's idea that **neurogenesis**, the production of new neurons, does not occur in the CNS after birth. Cajal's idea was widely accepted for many years. However, in science prevailing hypotheses are continuously challenged by new findings. Researchers investigating seemingly unrelated problems made observations that shed new light on the neurogenesis issue.

Since the 1970s Fernando Nottebohm at Rockefeller University has studied birdsong, including its neural basis. Nottebohm found that birds produce new neurons daily in the brain center that regulates their songs. His work was at first dismissed as a phenomenon peculiar to birds and not relevant to mammals.

Figure 41-2 Structure of a multipolar neuron

The cell body contains most of the organelles. Many dendrites and a single axon extend from the cell body. Schwann cells form a myelin sheath around the axon by wrapping their own plasma membranes around the neuron in jelly-roll fashion.

However, other investigators, notably psychologist Elizabeth Gould at Princeton University, have provided additional data that together have falsified Cajal's hypothesis. Gould demonstrated neuron proliferation in primates. She and her research team also discovered that stress damages the brain and inhibits mitosis in neurons. They stressed newborn rats by separating them from their mothers for up to 3 hours a day. The stressed rats did not learn how to cope with stress, and as adults they had fewer new neurons in certain areas of their brains than control rats. Neurobiologists now agree that neurogenesis does occur regularly in the adult mammalian brain, at least in certain areas of the hippocampus and in the lining of the lateral ventricles. The paradigm shift away from Cajal's long accepted hypothesis demonstrates the power and importance of the process of science.

Axons aggregate to form nerves and tracts

A **nerve** consists of hundreds or even thousands of axons wrapped together in connective tissue (FIG. 41-3). We can compare a nerve to a telephone cable. The individual axons correspond to the wires that run through the cable, and the sheaths and connective tissue coverings correspond to the insulation. Within the CNS, bundles of axons are called **tracts** or *pathways* rather than nerves.

Outside the CNS, a mass of neuron cell bodies is called a **ganglion** (plural, *ganglia*). Inside the CNS, a collection of cell bodies is called a **nucleus**, rather than a ganglion.

(a) A nerve consists of bundles of axons held together by connective tissue. The cell bodies belonging to the axons of a nerve are grouped in a ganglion.

Glial cells play critical roles in neural function

Glial cells collectively make up the *neuroglia* (literally, “nerve glue”). Glial cells were once thought to be passive cells that simply support and protect the neurons. Armed with more sophisticated technology, neurobiologists are discovering that glial cells communicate and carry out major regulatory functions.

More than 75% of the cells in the human CNS are glial cells. They account for only about 50% of the brain volume because they do not branch as extensively as neurons. Four types of glial cells are found in the vertebrate CNS: astrocytes, oligodendrocytes, ependymal cells, and microglia (TABLE 41-1).

Astrocytes, the most numerous glial cells, are star-shaped. These cells provide both physical support and nutrients for neurons. They help regulate the composition of the extracellular fluid in the CNS by removing excess potassium ions. This action helps maintain normal neuron excitability.

Some astrocytes position the ends of their long processes on blood vessels in the brain. In response, endothelial cells lining the blood vessels form *tight junctions* (see Fig. 5-23a) that prevent many potentially harmful substances in the blood from entering the brain tissue. This protective wall is the *blood–brain barrier*. Astrocytes also help regulate self-cleaning mechanisms in the brain that involve flushing out wastes with cerebrospinal fluid.

Neurobiologists have shown that astrocytes are functionally connected throughout the brain. These interesting glial cells participate in information signaling by coordinating activity among neurons. They communicate through *gap junctions* and with signaling molecules. Although astrocytes can generate

(b) SEM (false colored) of a cross section through a spinal nerve. The tissue was freeze-fractured to show the bundle of myelinated axons (purple) that make up the nerve. The blood vessel (red) in the center of the nerve contains red blood cells. A covering of connective tissue (epineurium) surrounds the nerve.

Figure 41-3 Structure of a myelinated nerve

Table 41-1 Functions of Glial Cells

Type of Glial Cell	Functions
ASTROCYTES 	Physically support neurons Help transfer nutrients to neurons Remove excess K^+, which helps regulate composition of extracellular fluid in CNS Induce blood vessels to form blood–brain barrier and help maintain the barrier Communicate with one another and with neurons Induce synapse formation and strengthen synaptic transmission by chemically signaling neurons Respond to neurotransmitters and help regulate neurotransmitter reuptake May link receptors in the brain associated with learning and memory Guide neurons during embryonic development
OLIGODENDROCYTES 	Form myelin sheaths around neurons in CNS May be important in learning and memory
EPENDYMAL CELLS 	Line cavities of CNS Help produce and circulate cerebrospinal fluid May function as neural stem cells
MICROGLIA 	Phagocytosis of bacteria and debris Release signaling molecules that mediate inflammation May play important role in regulating the number of neurons in the developing brain by destroying neurons that are not needed

only weak electrical signals, they communicate with one another and with neurons by means of chemical signals. Astrocytes appear to respond to neurotransmitters released by neurons. They also help regulate the reuptake of excess neurotransmitters from synapses. Astrocytes induce synapse formation and can strengthen activity of synapses in the brain. Their actions appear to be important in learning and memory.

Astrocytes play a role in development by guiding neurons to appropriate locations in the body. Certain astrocytes function as stem cells in the brain and spinal cord. These cells can give rise to new neurons, additional astrocytes, and certain other glial cells. Taken out of their normal environment in the adult mouse brain, astrocytes can give rise to cells of all germ layers (the embryonic tissue layers: ectoderm, mesoderm, and endoderm). Human astrocytes may someday be used to produce specific types of cells needed for treating various medical conditions.

Oligodendrocytes are glial cells that envelop neurons in the CNS, forming insulating myelin sheaths around them. Because myelin is an excellent electrical insulator, its presence speeds transmission of neural impulses. In the neurological disease **multiple sclerosis**, patches of myelin deteriorate at irregular intervals along axons in the CNS and are replaced by scar tissue. This damage interferes with conduction of neural impulses, and the victim suffers loss of coordination, tremor, and partial or complete paralysis of parts of the body. Multiple sclerosis affects more than 2 million people worldwide.

Do not confuse oligodendrocytes with Schwann cells. Although sometimes considered glial cells, Schwann cells are located outside the CNS. (Recall that Schwann cells form myelin sheaths around axons of many neurons that are part of the PNS.)

Ependymal cells are ciliated glial cells that line the internal cavities of the CNS. Ependymal cells help produce and circulate the *cerebrospinal fluid* that bathes the brain and spinal cord of vertebrates (discussed in Chapter 42). There is some evidence that ependymal cells function as neural stem cells, and that they have the potential to give rise to new neurons, as well as to glial cells.

Microglia are actually specialized macrophages (phagocytic cells that ingest and digest cell debris and bacteria). Microglia respond to signals from neurons and are important in mediating responses to injury or disease. These cells are found near blood vessels. When the brain is injured or infected, microglia multiply and move to the affected area. There they remove bacteria and cell debris by phagocytosis. In addition, they release signaling molecules (also produced by macrophages and certain other cells in the immune system) that mediate inflammation. Microglia appear to help regulate the number of neurons in the developing brain by destroying neurons that are not needed.

CHECKPOINT 41.2

- **VISUALIZE** Sketch a multipolar neuron and label the cell body, dendrites, axon, and synaptic terminals. Give the function of each structure.
- How is a neuron different from a nerve?
- What are the functions of astrocytes? of microglia?

41.3 Transmitting Information along the Neuron

LEARNING OBJECTIVES

- 4 Explain how the neuron develops and maintains a resting potential.
- 5 Compare a graded potential with an action potential, describing the production and transmission of each.
- 6 Contrast continuous conduction with saltatory conduction.

Most animal cells have a difference in electric charge across the plasma membrane: the electric charge inside the cell is more negative than the electric charge of the extracellular fluid. The plasma membrane is said to be electrically *polarized*, meaning that one side, or pole, has a different charge than the other side. When electric charges are separated in this way, a potential energy difference exists across the membrane.

The difference in electric charge across the plasma membrane gives rise to an *electrical gradient*. Voltage is the force that causes charged particles to flow between two points. The voltage measured across the plasma membrane is a form of potential energy called the **membrane potential**. If the charges are permitted to come together, they have the ability to do work. Thus, the cell can be thought of as a biological battery. In excitable cells, such as neurons and muscle cells, the membrane potential can change rapidly. Such changes can transmit signals to other cells.

Ion channels and pumps maintain the resting potential of the neuron

The membrane potential in a resting (not excited) neuron or muscle cell is its **resting potential**. The resting potential is generally expressed in units called *millivolts* (mV). (A millivolt equals one thousandth of a volt.) Like other cells that can produce electrical signals, the neuron has a resting potential of about 70 mV. By convention, this value is expressed as -70 mV because the cytosol close to the plasma membrane is negatively charged relative to the extracellular fluid (**FIG. 41-4a**).

Biologists can measure the potential across the membrane by placing one electrode inside the cell and a second electrode outside the cell and connecting them through a very sensitive voltmeter or oscilloscope. If you place both electrodes on the outside surface of the neuron, no potential difference between them is registered. (All points on the same side of the membrane have the same charge.) However, once one of the electrodes penetrates the cell, the voltage changes from zero to approximately -70 mV.

Two main factors determine the magnitude of the membrane potential: (1) differences in the concentrations between specific ions inside the cell and those in the extracellular fluid and (2) selective permeability of the plasma membrane to these ions. The distribution of ions inside neurons and in the extracellular fluid surrounding them is like that of most other cells in the body. The potassium ion (K^+) concentration is about 10 times greater inside the cell than outside the cell. In contrast, the sodium ion (Na^+) concentration is about 10 times greater

(b) Permeability of the neuron membrane. The membrane is less permeable to Na^+ than to K^+ . Passive ion channels allow K^+ to diffuse out along their concentration gradient. Potassium ions are mainly responsible for the voltage across the membrane. Sodium-potassium pumps in the plasma membrane actively pump Na^+ out of the cell and pump K^+ in. The plasma membrane is permeable to negatively charged Cl^- , and they contribute slightly to the negative charge. Large anions (A^-) such as proteins also contribute to the negative charge.

Figure 41-4 Resting potential

outside than inside. This asymmetric distribution of ions across the plasma membrane at rest is brought about by the action of selective ion channels and ion pumps. In vertebrate neurons (and skeletal muscle fibers), the resting membrane potential depends mainly on the diffusion of ions down their *concentration gradients* (see discussion of diffusion in Chapter 5).

Ions cross the plasma membrane by diffusion through ion channels

Recall that net movement of ions occurs from an area of higher concentration of that type of ion to one of lower concentration. Membrane proteins form ion channels that typically allow only specific types of ions to pass. Neurons have three types of ion channels: *passive ion channels*, *voltage-activated channels*, and *chemically activated ion channels*. **Passive ion channels** permit the passage of specific ions such as Na^+ , K^+ , Cl^- , and Ca^{2+} (FIG. 41-4b). Unlike voltage-activated and chemically activated ion channels, passive ion channels are not controlled by gates.

Potassium channels are the most common type of passive ion channel in the plasma membrane, and cells are more permeable to potassium than to other ions. In fact, in the resting neuron, the plasma membrane is up to 100 times more permeable to K^+ than to Na^+ . When pumped out of the neuron, Na^+ cannot easily pass back into the cell. However, K^+ pumped into the neuron easily diffuses out.

Potassium ions leak out through passive ion channels following their concentration gradient. As K^+ diffuse out of the neuron, they increase the positive charge in the extracellular fluid relative to the charge inside the cell. The resulting change in the electrical gradient across the membrane influences the flow of ions. This electrical gradient forces some of the positively charged potassium ions back into the cell.

The membrane potential at which the flow of K^+ inward (due to the electrical gradient) equals the flow of K^+ outward (because of the concentration gradient) is the **equilibrium potential** for K^+ . The equilibrium potential for any particular ion is a steady state in which opposing chemical and electrical flows are equal and there is no net movement of the ion. The equilibrium potential for K^+ in the typical neuron is -90 mV. The equilibrium potential for Na^+ is $+60$ mV; it differs from the equilibrium potential of K^+ because of the difference in concentration of Na^+ across the membrane (concentration is high outside and low inside the cell). Because the membrane is much more permeable to K^+ than to Na^+ , the resting potential of the neuron is closer to the potassium equilibrium potential than to the sodium equilibrium potential. (Remember that the resting potential of the neuron is about -70 mV.)

The resting potential is primarily established by the net flow of K^+ into the neuron. However, the net flow of Na^+ outward contributes to the resting potential. Because the plasma membrane is permeable to negatively charged chloride ions, Cl^- also contribute slightly. These ions accumulate in the cytosol close to the plasma membrane. Negative charges on large molecules such as proteins add to the negative charge in the cytosol. These large anions cannot cross the plasma membrane.

Ion pumping maintains the gradients that determine the resting potential

The neuron plasma membrane has very efficient **sodium–potassium pumps** that actively transport Na^+ out of the cell and K^+ into the cell (see Fig. 41-4b; also see Fig. 5-16). These pumps require ATP to pump Na^+ and K^+ against their concentration and electrical gradients. For every three Na^+ pumped out of the cell, two K^+ are pumped in. Thus, more positive ions are pumped out than in. The sodium–potassium pumps maintain a higher concentration of K^+ inside the cell than outside and a higher concentration of Na^+ outside than inside.

In summary, the development of the resting potential depends mainly on the diffusion of K^+ out of the cell. However, once the neuron reaches a steady state, net Na^+ diffusion into the cell is greater than net K^+ diffusion out of the cell. This situation is offset by the sodium–potassium pumps that pump three Na^+ out of the cell for every two K^+ pumped in.

Graded local signals vary in magnitude

Neurons are excitable cells. They respond to stimuli and can convert stimuli into nerve impulses. An electrical, chemical, or mechanical stimulus may alter the resting potential by increasing the membrane's permeability to sodium ions.

When a stimulus causes the membrane potential to become less negative (closer to zero) than the resting potential, that region of the membrane is **depolarized**. Because depolarization brings a neuron closer to transmitting a neural impulse, it is described as *excitatory*. In contrast, when the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized**. Hyperpolarization is *inhibitory*; it decreases the neuron's ability to generate a neural impulse.

A stimulus may change the potential in a relatively small region of the plasma membrane. Such a **graded potential** is a local response. It functions as a signal only over a very short distance because it fades out within a few millimeters of its point of origin. A graded potential varies in magnitude; that is, the potential charge varies depending on the strength of the stimulus applied. A larger stimulus causes a larger change in permeability and a greater change in membrane potential.

Axons transmit signals called action potentials

When a stimulus is strong enough, a rapid, large change in membrane potential occurs, depolarizing the membrane to a critical point known as the **threshold level**. At that point, the neuron fires a *nerve impulse*, or **action potential**, an electrical signal that travels rapidly down the axon into the synaptic terminals. All cells can generate graded potentials, but only neurons, muscle cells, and a few cells of the endocrine and immune systems can generate action potentials.

In a series of experiments in the 1940s, pioneering English researchers Alan Hodgkin and Andrew Huxley inserted electrodes into large axons found in squids. By measuring voltage changes as they varied ion concentrations, these investigators

showed that passage of Na^+ ions *into* the neuron and K^+ ions *out* of the neuron resulted in an action potential. The process of Na^+ rushing into the cell may be thought of as fueling the action, whereas the process of K^+ leaving the cell brakes the action potential. In 1963, Hodgkin and Huxley received the Nobel Prize in Physiology or Medicine for this research.

We now know that changes in voltage regulate specific **voltage-activated ion channels** (also called *voltage-gated ion channels*) in the plasma membrane of the axon and cell body. Biologists can study these channels by using the **patch clamp technique** to measure currents across a very small segment of the plasma membrane rather than across the entire membrane (FIG. 41-5). The patch of membrane measured is so small that it may contain a single channel.

Biologists have used certain toxins that affect the nervous system to investigate how membrane channels function. For example, the poison tetrodotoxin (TTX) binds to voltage-activated Na^+ channels, blocking the passage of Na^+ . Using TTX and other toxins, researchers were able to identify the channel protein. TTX was first isolated from the Japanese puffer fish, which is eaten as a delicacy (FIG. 41-6). In tiny amounts TTX tingles the taste buds, but a slightly larger amount can prevent breathing. (The Japanese government operates a certification program that teaches puffer fish chefs to carefully remove the organs containing the toxin.)

Investigators have established that voltage-activated ion channels have charged regions that act as gates. Voltage-activated Na^+ channels have two gates: an *activation gate* and an *inactivation gate* (FIG. 41-7a). Voltage-activated K^+ channels have a single gate (FIG. 41-7b).

Local anesthetics, such as procaine (novocaine) and lidocaine (Xylocaine) as well as cocaine, bind to voltage-activated Na^+ channels and block them. These blocked channels cannot open in response to depolarization, and the neuron cannot transmit an impulse through the anesthetized region. Signals do not reach the brain, so pain is not experienced.

An action potential is generated when the voltage reaches threshold level

The membrane of most neurons can depolarize by about 15 mV—that is, to a potential of about -55 mV—without initiating an action potential. However, when depolarization is greater than -55 mV, the threshold level is reached, and an action potential is generated. The neuron membrane quickly reaches zero potential and even *overshoots* to $+35$ mV or more as a momentary reversal in polarity takes place. The sharp rise and fall of the action potential is called a *spike*. FIGURE 41-8a on page 870 illustrates an action potential recorded by placing one electrode inside an axon and one just outside.

At resting potentials, activation gates of the voltage-activated Na^+ channels are closed, and Na^+ cannot pass into the neuron (FIG. 41-8b on page 870). Follow the steps illustrated in Figure 41-8b as you read about transmission of action potentials, repolarization, and return to the resting state. When the voltage reaches threshold level, the channel proteins change shape, opening the activation gates. Sodium ions can then flow through the voltage-activated Na^+ channels. As a

WHY IS IT USED? The patch clamp technique allows researchers to study the action of a single ion channel over time, even in very small cells. This research method was developed in the mid-1970s by Erwin Neher and Bert Sakmann, both of the Max Planck Institute in Germany. They were awarded a Nobel Prize in Physiology or Medicine in 1991 for this work.

HOW IS IT DONE? The tip of a micropipette is tightly sealed to a patch of membrane so small that it generally contains only a single ion channel. The flow of ions through the channel can be measured using an extremely sensitive recording device. Cell biologists have found that the current flow is intermittent and corresponds to the opening and closing of the ion channel. The permeability of the channel affects the magnitude of the current.

Figure 41-5 The patch clamp technique

The patch clamp technique has been modified in many ways and has been applied to studies in both plants and animals of the roles of ion channels in a wide range of cellular processes. For example, neuroscientists once thought that transmitting action potentials was a very inefficient process. They thought that there was a high degree of overlap between the time that Na^+ rush into the cell and K^+ move out of the cell. This process would be a waste of energy because it would be like stepping on the gas and brake pedals at the same time. Henrik Alle, a neuroscientist at the Max Planck Institute for Brain Research in Frankfurt, Germany, and his colleagues used the patch clamp technique to record currents in neurons of the learning and memory areas of rat brains. They found that the flows of Na^+ and K^+ were almost completely separated in time. Na^+ have almost finished entering the neuron before K^+ ions begin to exit. In contrast to earlier estimates of 30% efficiency for transmission of signals, neurons may transmit action potentials with more than 70% efficiency.

result, the inside of the neuron becomes positively charged relative to the fluid outside the plasma membrane, generating an action potential. Inactivation gates that are open in the resting neuron close slowly in response to depolarization. Sodium ions can pass through the channel only during the brief period when both activation and inactivation gates are open.

The generation of an action potential depends on a **positive feedback system**. (Recall from Chapter 39 that in a positive feedback system, a change in some condition triggers a response that *intensifies* the change.) As just discussed, when a neuron becomes depolarized, voltage-activated Na^+ channels open, increasing the membrane permeability to Na^+ .

Sodium ions diffuse into the cell, moving from an area of higher concentration to an area of lower concentration. As Na^+ flow into the cell, the cytosol becomes positively charged relative to the extracellular fluid. The positive charge further depolarizes the neuron so that more voltage-activated Na^+ channels open, which increases membrane permeability to Na^+ .

The neuron repolarizes and returns to a resting state

After a certain period, inactivation gates close in the Na^+ channels, and the membrane again becomes impermeable to

Figure 41-6 Fish with tetrodotoxin

Like the Japanese puffer fish (*Fugu rubripes*), this closely related porcupine fish has tetrodotoxin in its internal organs. This fish can inflate its body by swallowing air or water. When it is larger and rounder, it is safer from many predators.

Na^+ . This inactivation begins the process of **repolarization**, during which the membrane potential returns to its resting level. Voltage-activated K^+ channels slowly open in response to depolarization. When Na^+ have almost stopped rushing into the neuron, K^+ channels open, and K^+ leak out of the neuron. This decrease in intracellular K^+ returns the interior of the membrane to its relatively negative state, repolarizing the membrane. Voltage-activated K^+ channels remain open until the resting potential has been restored.

As a *wave of depolarization* moves down the membrane of the neuron, the normal polarized state is quickly re-established behind it. The entire process—depolarization and then repolarization—can take place in less than 1 millisecond.

During the millisecond or so in which it is depolarized, the axon membrane is in an **absolute refractory period**: it cannot transmit another action potential no matter how great a stimulus is applied because the voltage-activated Na^+ channels are inactivated. Until their gates are reset, they cannot open again. When enough Na^+ channel

gates have been reset, the neuron enters a *relative* refractory period that lasts for a few more milliseconds. During this period, the axon can transmit impulses, but the threshold is higher (less negative). Even with the limits imposed by their refractory periods, most neurons can transmit several hundred impulses per second.

In summary, neural action proceeds as follows:

neuron in resting state → stimulus causes depolarization → threshold reached → action potential transmits signal → repolarization and return to resting state

The action potential is an all-or-none response

Any stimulus too weak to depolarize the plasma membrane to threshold level cannot fire the neuron. It merely sets up a local signal that fades and dies within a few millimeters from the point of stimulus. Only a stimulus strong enough to depolarize the membrane to its critical threshold level results in transmission of an impulse along the axon. An action potential is an **all-or-none response** because either it occurs or it does not. No variation exists in the strength of a single impulse.

If the all-or-none law is valid, how can we explain differences in the levels of intensity of sensations? After all, we have no difficulty distinguishing between the pain of a severe toothache and that of a minor cut on the arm. We can explain this apparent inconsistency by understanding that the intensity of sensation depends on several factors, including the *number of neurons stimulated* and their *frequency of discharge*. For example, suppose that you burn

(a) Sodium channels. In the resting state, voltage-activated Na^+ channels are closed (*left*). When the voltage reaches threshold level, activation gates open quickly, allowing Na^+ to pass into the cell (*right*). After a certain time, inactivation gates close, blocking the channels (*not shown*). Inactivation gates are open when a neuron is in the resting state; they close slowly in response to depolarization. The ion channel is open only during the brief period when both activation and inactivation gates are open.

(b) Potassium channels. Voltage-activated K^+ channels have activation gates that open slowly in response to depolarization. The activation gates close after the resting potential has been restored. Potassium channels have no inactivation gates.

Figure 41-7 Voltage-activated ion channels

Key Point

When the neuron plasma membrane is depolarized to threshold level, voltage-activated Na^+ channels open and Na^+ rush into the neuron, causing greater depolarization; an action potential is generated.

(a) **Action potential.** When the axon depolarizes to about -55 mV, an action potential is generated. (The numerical values vary for different nerve cells.)

(b) The action of ion channels in the plasma membrane determines the state of the neuron.

Figure 41-8 Action potentials depend on voltage-gated ion channels
Generation of an action potential depends on the action of voltage-gated sodium and potassium ion channels in the plasma membrane.

PREDICT One of the toxins (charybdotoxin) produced by scorpions blocks K^+ channels. What effect would this toxin have on the action of a neuron?

your hand. If a large area is burned, more pain receptors are stimulated and more neurons become depolarized. Also, each neuron transmits more action potentials per unit of time.

An action potential is self-propagating

Once initiated, an action potential continues along the neuron. During depolarization, the affected area of the membrane

is more positive relative to adjacent regions where the membrane is still at resting potential. The difference in potentials between active and resting membrane regions causes ions to flow between them (an electric current). The flow of Na^+ into the adjacent region induces the opening of voltage-activated Na^+ channels in that area of the membrane (FIG. 41-9). The process is repeated like a chain reaction until the end of the axon is

reached. Thus, an action potential is a **wave of depolarization** that travels down the length of the axon.

Transmission of an action potential is sometimes compared with a flame moving along a trail of gunpowder. Once the gunpowder is ignited at one end of the trail, the flame moves steadily to the other end by igniting the powder particles ahead of it. An amazing difference is that after a brief refractory period, the neuron recovers and is able to transmit another action potential.

Several factors determine the velocity of an action potential

Compared with the flow of electrons in electrical wiring or the speed of light, a nerve impulse travels rather slowly. Most axons transmit impulses at about 1 to 10 m per second. The smooth, progressive impulse transmission just described, called *continuous conduction*, occurs in unmyelinated neurons. In these axons, the speed of transmission is proportional to the diameter

of the axon. Axons with larger diameters transmit faster than those with smaller diameters because an axon with a large diameter presents less internal resistance to the ions flowing along its length. Squids and certain other invertebrates have giant axons, up to 1 mm in diameter, which allow them to respond rapidly when escaping from predators.

In vertebrates, another strategy that speeds transmission has evolved—myelinated neurons. Myelin acts as an effective electrical insulator around the axon. However, the axon is not myelinated at the nodes of Ranvier. At these nodes, the plasma membrane of the axon makes direct contact with the surrounding extracellular fluid. Voltage-activated Na^+ and K^+ channels are concentrated at the nodes. In fact, in myelinated neurons, ion movement across the membrane occurs only at the nodes.

The ion activity at an active node results in diffusion of ions along the axon that depolarize the next node. The action potential appears to jump from one node of Ranvier to the next (FIG. 41-10). This type of impulse transmission is known as **saltatory conduction** (from the Latin word *saltus*, meaning “to leap”).

In myelinated neurons, the distance between successive nodes of Ranvier affects speed of transmission. When nodes are farther apart, less of the axon must depolarize,

- 1 An action potential is transmitted as a wave of depolarization that travels down the axon. At the region of depolarization, Na^+ diffuse into the cell.

- 2 As an action potential progresses along the axon, repolarization occurs quickly behind it.

Figure 41-9 Transmission of an action potential along the axon

When the dendrites (or cell body) of a neuron are stimulated sufficiently to depolarize the membrane to its threshold level, a strong pulse of voltage change travels down the axon. This pulse is the action potential.

and the axon conducts the impulse faster. Using saltatory conduction, a myelinated axon can conduct an impulse up to 50 times faster than the fastest unmyelinated axon.

Saltatory conduction has another advantage over continuous conduction: it requires less energy. Ions move across the plasma membrane only at the nodes, so fewer Na^+ and K^+ are displaced. As a result, the sodium–potassium pumps do not expend as much ATP to re-establish resting conditions each time an impulse is conducted.

✓ CHECKPOINT 41.3

- How do ion channels and sodium–potassium pumps contribute to the resting potential?
- Describe the sequence of events that occurs when threshold level is reached in a neuron.
- Contrast an action potential with a graded potential.
- What are the benefits of saltatory conduction compared with continuous conduction?

41.4 Transmitting Information across Synapses

🎯 LEARNING OBJECTIVES

- 7 Describe the actions of the neurotransmitters identified in this chapter.
- 8 List the sequence of events that take place in synaptic transmission and draw diagrams to support your description.
- 9 Compare excitatory and inhibitory signals and their effects.

A **synapse** is a junction between two neurons or between a neuron and an effector (a muscle or gland cell). A neuron that *terminates* at a specific synapse is called a **presynaptic neuron**, whereas a neuron that *begins* at that synapse is a **postsynaptic neuron**. Note that these terms are relative to a specific synapse. A neuron that is postsynaptic with respect to one synapse may be presynaptic to the next synapse in the sequence.

Signals across synapses can be electrical or chemical

Based on how presynaptic and postsynaptic neurons communicate, two types of synapses have been identified: electrical synapses and chemical synapses. In an **electrical synapse**, the presynaptic and postsynaptic neurons occur very close together (within 2 nm of one another) and form *gap junctions* (see Fig. 5-23c). The interiors of the two neurons are physically connected by a protein channel. Electrical synapses let ions pass from one cell to another, permitting an impulse to be directly and rapidly transmitted from a presynaptic to a postsynaptic neuron. The escape responses of many animals involve electrical synapses. For example, the “tail-flick” escape response of the

Key Point

In saltatory conduction, Na^+ rapidly diffuse from one node of Ranvier to the next. Action potentials appear to leap from node to node.

Figure 41-10 Saltatory conduction

This sequence of diagrams (steps 1 through 4) illustrates transmission of an action potential in a myelinated neuron. The *arrows* in the axons indicate diffusion of Na^+ .

PREDICT How might the disease multiple sclerosis affect transmission of action potentials along a myelinated neuron?

crayfish involves giant neurons in the nerve cord that form electrical synapses with large motor neurons. The motor neurons signal muscles in the abdomen to contract. Electrical synapses are important in the mammalian nervous system as well. For example, many interneurons communicate by way of electrical synapses. They are also found in cardiac muscle and in the retina.

The majority of synapses are **chemical synapses**. Pre-synaptic and postsynaptic neurons are separated by a space, the **synaptic cleft**, which is about 20 nm wide (less than one-millionth of an inch). Depolarization is a property of the plasma membrane, so when an action potential reaches the end of the axon, it cannot jump the gap. The electrical signal must be converted into a chemical one.

When an action potential reaches a synaptic terminal, it triggers the release of a **neurotransmitter**, a chemical messenger that conducts the neural signal across the synapse. Neurotransmitter molecules then bind to receptors that are chemically activated ion channels in the membrane of the postsynaptic neuron. This binding triggers specific gated ion channels to open (or close), resulting in changes in permeability of the postsynaptic membrane. When a postsynaptic neuron reaches its threshold level of depolarization, it transmits an action potential.

Neurons use neurotransmitters to signal other cells

Neurotransmitters signal other neurons, muscle fibers, or gland cells. About 100 different neurotransmitters are known or suspected. We can categorize them in several chemical groups, including acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters (**TABLE 41-2**).

Acetylcholine is a low-molecular-weight neurotransmitter that is released from motor neurons and triggers muscle contraction. Acetylcholine is also released by some neurons in the brain and in the autonomic nervous system (see *Inquiring About: Alzheimer's Disease*; also see Chapter 42). Cells that release acetylcholine are called **cholinergic neurons**.

Neurons that release norepinephrine are called **adrenergic neurons**. **Norepinephrine**, **epinephrine**, and the neurotransmitter **dopamine** are **catecholamines**. The catecholamines and the neurotransmitters **serotonin** and **histamine** belong to a class of compounds called **biogenic amines**. Biogenic amines affect mood, and their imbalance has been linked to several disorders, including major depression, anxiety disorders, attention deficit hyperactivity disorder (ADHD), and schizophrenia.

Several amino acids function as neurotransmitters. **Glutamate** is the major excitatory neurotransmitter in the brain. One type of glutamate receptor is the target of several mind-altering drugs, including phencyclidine (known as PCP or “angel dust”).

The amino acid **glycine** and a modified amino acid, **gamma-aminobutyric acid (GABA)**, are neurotransmitters that inhibit neurons in the spinal cord and brain. Glycine is the main inhibitory neurotransmitter in the spinal cord. GABA is the neurotransmitter used at most rapid inhibitory synapses throughout the brain. Many drugs that reduce anxiety enhance the actions of GABA by permitting lower concentrations of GABA to open Cl^- channels. These drugs include benzodiazepines, such as diazepam (Valium) and alprazolam (Xanax), and barbiturates, such as phenobarbital.

Neuropeptides, such as endorphins and enkephalins, appear to function mainly as **neuromodulators**, messenger molecules that stimulate long-term changes that enhance or inhibit synaptic function. Some neurobiologists consider

them a group of neurotransmitters, but others classify them as a separate group. **Endorphins**, such as *beta-endorphin*, and **enkephalins** are the body's own endogenous opioids. Opiate drugs—for example, morphine and codeine—are powerful analgesics, drugs that relieve pain without causing loss of consciousness. Endorphins and enkephalins bind to opioid receptors (the same receptors to which opiate drugs bind) and block pain signals. Opioids modulate the effect of other neurotransmitters, including **substance P**, which activates pathways that transmit pain signals from certain sensory neurons to the CNS. (We discuss pain perception in Chapter 43.)

The signaling molecule **nitric oxide (NO)** is a gas that diffuses across cell membranes. It can transmit information from the postsynaptic neuron to the presynaptic neuron, the opposite direction of transmission from other neurotransmitters. Thus, it acts as a *retrograde messenger* at some synapses.

Neurotransmitters bind with receptors on postsynaptic cells

Neurotransmitters are stored in synaptic terminals within hundreds of small membrane-enclosed sacs called *synaptic vesicles* (**FIG. 41-11a** on page 876). Each time an action potential reaches a synaptic terminal, voltage-gated Ca^{2+} channels open. Calcium ions from the extracellular fluid then flow into the synaptic terminal. The Ca^{2+} induce synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter molecules into the synaptic cleft by exocytosis (**FIG. 41-11b** on page 876; also see Chapter 5).

Neurotransmitter molecules diffuse across the synaptic cleft and bind with specific receptors on the dendrites or cell bodies of postsynaptic neurons (or on the plasma membranes of effector cells). Many neurotransmitter receptors are chemically activated ion channels known as **ligand-gated channels** (see Chapter 6). When the neurotransmitter, the *ligand*, binds with the receptor, the ion channel opens (**FIG. 41-11c** on page 876). (Recall that a ligand is a molecule that binds to a specific site in a receptor.) The acetylcholine receptor, for example, is a ligand-gated ion channel that permits the passage of Na^+ and K^+ .

Some neurotransmitters, such as serotonin, operate by a different mechanism. They work indirectly through a **second messenger**. Binding of the neurotransmitter with a receptor activates a **G protein**. The G protein then activates an enzyme, such as adenylyl cyclase, in the postsynaptic membrane. Adenylyl cyclase converts ATP to **cyclic AMP (cAMP)**, which acts as a second messenger (see Chapters 6 and 49). Cyclic AMP activates a kinase that phosphorylates a protein, which then closes K^+ channels.

For a postsynaptic neuron to repolarize quickly, any excess neurotransmitter in the synaptic cleft must be removed. Some neurotransmitters are inactivated by enzymes. For example, the enzyme acetylcholinesterase degrades excess acetylcholine into its chemical components, choline and acetate. Other neurotransmitters, such as the biogenic amines, are actively transported back into the synaptic terminals, a process known as *reuptake*. These neurotransmitters are repackaged in vesicles and recycled.

Many drugs inhibit the reuptake of neurotransmitters. For example, some antidepressant medications are selective serotonin reuptake inhibitors (SSRIs). SSRIs such as fluoxetine

Table 41-2 Selected Neurotransmitters

Neurotransmitter	Site of Action	Action	Comments
ACETYLCHOLINE	CNS, neuromuscular junctions	Excitatory effect on skeletal muscle; inhibitory effect on cardiac muscle; excitatory or inhibitory at other sites	Important role in learning and memory; concentration decreases in the brain during the progression of Alzheimer's disease; helps regulate both neural and immune system function
BIOGENIC AMINES			
Norepinephrine	CNS, PNS	Excitatory or inhibitory; concentration in brain affects mood, sleep, wakefulness, attention; mainly inactivated by reuptake into axon terminal	Amphetamines stimulate release and block their reuptake; certain antidepressants also block reuptake; Ritalin (methylphenidate) stimulates release
Dopamine	CNS	Helps maintain balance between excitation and inhibition of neurons; important in motor function; concentration in brain affects mood involved in motivation and reward	Abnormal amounts in attention-deficit disorder and schizophrenia; amount reduced in Parkinson's disease; amphetamines and cocaine stimulate release and cocaine also inhibits reuptake
Serotonin (5-hydroxy-tryptamine, 5-HT)	CNS	Excitatory effect on pathways that control muscle action; inhibitory effect on sensory pathways; helps regulate food intake, sleep, and wakefulness; affects mood	Concentration highest during alert states; concentration lowest during sleep; many antidepressants, for example, Prozac (fluoxetine) and Zoloft (paroxetine), block serotonin reuptake
AMINO ACIDS			
Glutamate	CNS, invertebrate neuromuscular junctions	Principal excitatory neurotransmitter in vertebrate brain; functions in learning and memory; excitatory effect at invertebrate neuromuscular junctions	THC, the main psychoactive ingredient of cannabis, decreases glutamate release
Gamma-aminobutyric acid (GABA)	CNS, invertebrate neuromuscular junctions	Major inhibitory neurotransmitter in mammalian CNS	Barbiturates and benzodiazepines increase effect of GABA
NEUROPEPTIDES			
Endorphins and enkephalins (opioids)	CNS, PNS	Endogenous opiates; bind with opiate receptors; inhibit release of substance P—this action inhibits pain	Morphine-like
Substance P	CNS, PNS	Activates pathways that transmit pain signals	
GASEOUS NEUROTRANSMITTERS			
Nitric oxide, carbon monoxide, hydrogen sulfide	Most neurons?	Diffuse across cell membranes; retrograde messengers; transmit signals from postsynaptic to presynaptic neurons	

(Prozac) and escitalopram (Lexapro) selectively inhibit the reuptake of serotonin in the brain. This action concentrates serotonin in the synaptic cleft, elevating mood. A few antidepressants inhibit the reuptake of both serotonin and norepinephrine or serotonin and dopamine.

Activated receptors can send excitatory or inhibitory signals

A postsynaptic neuron may have receptors for several types of neurotransmitters. Some of its receptors may be excitatory, and others may be inhibitory. As a result, the same neurotransmitter can have different effects depending on the type of postsynaptic receptor with which it combines. For example, acetylcholine has an excitatory effect on skeletal muscle and an inhibitory effect on cardiac muscle.

When neurotransmitter molecules bind to receptors, the activated receptor can directly or indirectly open or close ion channels; this action changes the permeability of the

postsynaptic membrane to certain ions. The resulting redistribution of ions changes the electrical potential of the membrane, and the membrane may depolarize. For example, when neurotransmitter molecules combine with receptors that open Na^+ channels, the resulting influx of Na^+ partially depolarizes the membrane. If sufficiently intense, a local depolarization can set off an action potential.

A change in membrane potential that brings the neuron closer to firing is called an **excitatory postsynaptic potential (EPSP)**. Imagine that sufficient sodium ions enter to change the membrane potential from -70 to -60 mV. The membrane would be only -5 mV away from threshold. Under such conditions, an additional relatively weak stimulus, causing a small influx of Na^+ , can cause the neuron to fire. *Note that unlike action potentials, postsynaptic potentials are graded responses.*

Some neurotransmitter–receptor combinations hyperpolarize the postsynaptic membrane, causing the membrane potential to become more negative. Because such an action takes the neuron farther away from the firing level, a potential change in

Inquiring About

Alzheimer's Disease

What is Alzheimer's disease, and what causes it? **Alzheimer's disease (AD)** is a progressive, degenerative brain disorder in which neural signaling is disrupted and neurons become damaged and die prematurely. Alzheimer's disease is the leading cause of senile dementia, the loss of memory, judgment, and ability to reason that is sometimes associated with aging. The first symptom of AD is mild cognitive impairment, typically a problem with short-term memory. As the disease progresses, the ability to read, write, and think logically becomes compromised, and long-term memory is affected. Eventually, the AD patient loses the ability to carry on routine daily activities, such as dressing, bathing, and eating, and may no longer recognize family members and close friends. Patients typically die within 10 to 12 years of diagnosis.

Worldwide, more than 35 million people are affected by AD, and more than 5 million people in the United States suffer from this disease. One in eight older individuals in the United States has AD, and this disease is the sixth leading cause of death. According to the national Alzheimer's Association (alz.org), AD is the only one of the top 10 causes of death in the United States that cannot be prevented or cured (or even slowed).

Only 4% of those with AD are under age 65. These early-onset cases are caused by mutations in one of three genes. There is some evidence that you can reduce your risk for AD by engaging in regular physical exercise, pursuing higher education, and working in a profession that is cognitively challenging, staying cognitively active, and interacting socially with other people.

AD typically develops over several decades. One startling study demonstrated that a person's

writing early in life can predict the disease. Young adults whose writings had a lower density of ideas were more likely to develop the disease than those whose density of ideas was higher. Early changes in the brain can now be detected by positron emission tomography scans, magnetic resonance imaging, and spinal taps years before AD symptoms are apparent (see Figure 1).

In AD, neurons are damaged in the cerebral cortex and hippocampus, areas of the brain important in thinking and remembering. Neurons that secrete the neurotransmitter acetylcholine are especially affected. Three abnormalities that develop in brain tissue as humans age are especially characteristic of AD: amyloid plaques, neurofibrillary tangles, and death of neurons. Understanding the biochemistry and genetic basis of both plaques and tangles may provide clues to the causes and cures of AD.

Amyloid plaques were first identified in autopsied brains in 1906 by Alois Alzheimer, a German physician. These plaques are extracellular deposits of a peptide called amyloid-beta ($\text{amyloid-}\beta$) that are surrounded by degenerating dendrites and axons. Researchers found that amyloid- β is cut from a precursor protein called β -APP, a large protein in neuron plasma membranes. Normal amyloid- β molecules have 40 amino acids. However, about 10% of the peptides produced have two additional amino acids. This longer peptide appears to form the plaques. Neurons near these plaques appear swollen and misshapen. Microglia are typically present, suggesting an attempt to remove the damaged cells or the plaques themselves. The microglia cause inflammation and release toxic compounds that damage nearby neurons. The abnormal peptide appears to disrupt calcium

regulation, which destroys neurons in the brain. There is also evidence that amyloid- β damages mitochondrial enzymes, releasing harmful free radicals.

Amyloid- β and its toxic effects may lead to formation of **neurofibrillary tangles**. These tangles, which form in the neuron cytoplasm, are another piece of the AD puzzle. The cytoskeletal protein known as *tau* normally associates with the protein tubulin, which forms microtubules. According to one hypothesis, amyloid- β interferes with the way the tau protein binds to microtubules, resulting in abnormal microtubules that cannot effectively transport materials through axons. Abnormal tau proteins accumulate in the cytoplasm, forming fibrous deposits that make up the neurofibrillary tangles (see Figure 2). These tangles interfere with neural signaling. Researchers have suggested that tau proteins, like prions, can become misfolded. These misfolded proteins can then cause other tau proteins to misfold. (See the discussion of prions in Chapter 24.)

AD is currently treated with two types of drugs. The first type—for example, Aricept and Exelon—inhibits the enzyme acetylcholinesterase. This action slows the breakdown of acetylcholine, a neurotransmitter that plays a role in memory and thought. The second type of drug, memantine (Namenda), affects glutamate, a neurotransmitter important in learning and memory. Namenda-type drugs slow cognitive decline. However, these drugs do not prevent the eventual damage that occurs in the brain.

Several new drugs are being developed. For example, a vaccine (AADvac1) in clinical trials stimulates the immune system to attack an abnormal tau protein, which may slow or stop the disease process.

Figure 1 These fluorodeoxyglucose (FDG)-PET scans measure glucose metabolism. FDG-PET scanning is one of the major methods used by the Alzheimer's Disease Neuroimaging Initiative (ADNI) to track progression of Alzheimer's disease. Orange and yellow colors indicate metabolic activity. Note reduced metabolic activity in the PET scan image of the brain of a patient with Alzheimer's disease.

Figure 2 Brain tissue from the cerebral cortex of a patient with Alzheimer's disease, showing characteristic amyloid plaques (rounded brown areas) and neurofibrillary tangles (dark teardrop shapes).

Key Point

At most synapses the action potential cannot jump across the synaptic cleft between the two neurons. This problem is solved by chemical signaling across synapses.

Figure 41-11 Neural signaling across a synapse

PREDICT What would be the effect of blocking the receptors on the postsynaptic neuron?

this direction is called an **inhibitory postsynaptic potential (IPSP)**. For example, if the membrane potential changes from -70 to -80 mV, the membrane is farther away from threshold, and a stronger stimulus is required to fire the neuron.

Like an EPSP, an IPSP can be produced in several ways. Two types of GABA receptors are known to produce IPSPs. When GABA binds to a GABA_B receptor, K⁺ channels open. As K⁺ diffuse out, the neuron becomes more negative, hyperpolarizing the membrane. Activated GABA_A receptors produce IPSPs by opening Cl⁻ channels. In this case, the influx of negative ions hyperpolarizes the membrane. Although the mechanisms are different, the inhibiting effect of GABA is the same in both cases.

In summary, neural signaling across synapses involves the following sequence of events:

action potential reaches synaptic terminal → calcium ions enter synaptic terminal → synaptic vesicles release neurotransmitter into the synaptic cleft → neurotransmitter diffuses across synaptic cleft → neurotransmitter binds with receptors in membrane of postsynaptic neuron → ion channels open or close, resulting in depolarization or hyperpolarization of postsynaptic membrane

CHECKPOINT 41.4

- What are some functions of biogenic amines? of GABA?
- **VISUALIZE** Sketch the sequence of events that takes place at a chemical synapse.
- How are EPSPs produced? IPSPs?

41.5 Neural Integration

LEARNING OBJECTIVE

- 10** Define *neural integration* and describe how a postsynaptic neuron sums incoming stimuli and “decides” whether to fire.

Each neuron may synapse with hundreds of other neurons. Indeed, thousands of synaptic terminals of presynaptic neurons may cover as much as 40% of a postsynaptic neuron’s dendritic surface and cell body. It is the job of the dendrites and the cell body of every neuron to integrate the messages that continually bombard them.

Neural **integration** is the process of summing, or integrating, incoming signals. EPSPs and IPSPs are produced continually in postsynaptic neurons, and IPSPs cancel the effects of some EPSPs. It is important to remember that each EPSP and IPSP is not an all-or-none response. Rather, each is a graded response that does *not* travel like an action potential but may be added to or subtracted from other EPSPs and IPSPs.

As the membrane of the postsynaptic neuron continuously updates its molecular tabulations, the neuron may be inhibited or brought to threshold level. This mechanism integrates hundreds of signals (EPSPs and IPSPs) before an action potential is actually transmitted along the axon of a

postsynaptic neuron. Local responses permit the neuron and the entire nervous system a far greater range of response than would be possible if every EPSP generated an action potential.

Postsynaptic potentials are summed over time and space

Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. One EPSP is usually too weak to trigger an action potential by itself. Its effect is below threshold level. However, even though sub-threshold EPSPs do not produce an action potential, they do affect the membrane potential. EPSPs can be added together in a process called **summation** (FIG. 41-12).

Temporal summation occurs when a presynaptic neuron fires multiple times in rapid succession, resulting in repeated stimulation of a postsynaptic neuron. New EPSPs develop before previous EPSPs have decayed. The summation of several EPSPs may bring the neuron to the critical firing level.

Spatial summation can also bring the postsynaptic neuron to threshold level. **Spatial summation** is the summing of several postsynaptic potentials resulting when closely spaced presynaptic neurons release neurotransmitter simultaneously. The postsynaptic neuron may be stimulated at multiple regions at the same time.

Neurons sum IPSPs as well as EPSPs. As IPSPs occur, they move the membrane potential farther away from threshold.

Where does neural integration take place?

On a molecular level, every neuron tabulates the thousands of bits of information that continuously bombard it. In vertebrates more than 90% of the neurons in the body are located in the CNS, so most neural integration takes place there, within the brain and spinal cord. These neurons are responsible for making most of the “decisions.” The brain and spinal cord are examined in some detail in the next chapter.

CHECKPOINT 41.5

- What is neural integration?
- How do temporal and spatial summation differ?
- Where does most neural integration take place in vertebrates?

41.6 Neural Circuits: Complex Information Signaling

LEARNING OBJECTIVE

- 11** Distinguish between convergence and divergence, and explain why each is important to the functioning of neural circuits.

Figure 41-12 Neural integration

E_1 and E_2 are excitatory stimuli. I represents an inhibitory stimulus.

(a) Subthreshold (no summation).

Each stimulus is at a subthreshold level, so no action potential is generated.

(b) Temporal summation.

The second EPSP occurs before the first dies off, so the two EPSPs are summed. An action potential is generated.

(c) Spatial summation.

EPSPs generated by input from two different presynaptic neurons are summed.

(d) Spatial summation of EPSPs and IPSPs.

EPSPs and IPSPs are also summed and can cancel each other out.

The CNS contains millions of neurons, but it is not just a tangled mass of nerve cells. Its neurons are functionally arranged in specific pathways, or **neural circuits**. A neural circuit typically consists of one or more afferent neurons, one or more interneurons, and one or more efferent neurons.

Neural circuits are organized into *neural networks*. Although each network has some specific characteristics, the neural circuits in all the networks share many organizational features. For example, convergence and divergence are characteristic of them all.

In **convergence** of neural input, a single neuron receives converging signals (inputs) from two or more presynaptic neurons (FIG. 41-13a). An interneuron in the spinal cord, for instance, may receive converging information from sensory neurons entering the spinal cord, from neurons bringing information from various parts of the brain, and from neurons coming from different levels of the spinal cord. Information from all these sources must be integrated before an action

potential is transmitted and an appropriate motor neuron is stimulated.

In **divergence** of neural input, a single presynaptic neuron makes connections with many postsynaptic neurons (FIG. 41-13b). Each presynaptic neuron may branch and synapse with thousands of different postsynaptic neurons. For example, a single neuron transmitting an impulse from the motor area of the brain may make connections with hundreds of interneurons in the spinal cord, and each of them may diverge, in turn, so that hundreds of muscle fibers are stimulated.

CHECKPOINT 41.6

- VISUALIZE** Draw simple sketches that contrast convergence of neural input with divergence of neural input.

(a) Convergence of neural input.

Several presynaptic neurons synapse with one postsynaptic neuron.

(b) Divergence of neural output.

A single presynaptic neuron synapses with many postsynaptic neurons.

Figure 41-13 Neural circuits

Summary: Focus on Learning Objectives

41.1 Neural Signaling: An Overview (page 861)

1 Describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors that brings about the actual response.

- Neural signaling involves (1) **reception** of information by a sensory receptor; (2) **neural transmission** by an **afferent neuron** to the **central nervous system (CNS)**, which consists of the brain and spinal cord; (3) **integration** by **interneurons** in the central nervous system; (4) transmission by an **efferent neuron** to other neurons or to an effector; and (5) action by **effectors**, the muscles and glands that bring about the actual **response** to the stimulus. Sensory receptors and neurons outside the CNS make up the **peripheral nervous system (PNS)**.

41.2 Neurons and Glial Cells (page 862)

2 Draw and label a typical neuron and give the function of each of its parts.

- Neurons** are specialized to receive stimuli and transmit electrical and chemical signals. In a typical neuron, a **cell body** contains the nucleus and most of the organelles. Many branched **dendrites** extend from the cell body; they are specialized to receive stimuli and send signals to the cell body.
- The single long **axon** extends from the cell body and forms branches called **axon collaterals**. The axon transmits signals into its **terminal branches**, which end in synaptic terminals.
- Many axons are surrounded by an insulating **myelin sheath**. In the PNS the myelin sheath is formed by **Schwann cells**. **Nodes of Ranvier** are gaps in the sheath between successive Schwann cells.
- A **nerve** consists of several hundred axons wrapped in connective tissue; a **ganglion** is a mass of neuron cell bodies in the PNS.

3 Identify the main types of glial cells and describe the functions of each.

- Glial cells** support and nourish neurons and are important in neural communication. **Astrocytes** are glial cells that physically support neurons. They help regulate the composition of the extracellular fluid in the CNS by taking up excess potassium ions. Astrocytes communicate with one another and with neurons; they also induce and stabilize synapses.

- Oligodendrocytes** are glial cells that form myelin sheaths around axons in the CNS. **Ependymal cells** line cavities in the CNS and help produce and circulate cerebrospinal fluid. **Microglia** are phagocytic cells.

41.3 Transmitting Information along the Neuron (page 865)

4 Explain how the neuron develops and maintains a resting potential.

- Neurons use electrical signals to transmit information along axons. The plasma membrane of a resting neuron, one that is not transmitting an impulse, is **polarized**. The inner surface of the plasma membrane is negatively charged relative to the extracellular fluid just outside the membrane. The voltage measured across the plasma membrane is the **membrane potential**.
- The **resting potential** is the potential difference of about -70 mV that exists across the membrane. The magnitude of the resting potential is determined by (1) differences in concentrations of specific ions (mainly Na^+ and K^+) inside the cell relative to the extracellular fluid and (2) selective permeability of the plasma membrane to these ions.
- Ions pass through specific **passive ion channels**. K^+ leak out more readily than Na^+ can leak in. The resting potential is mainly due to the net flow of K^+ out of the neuron. Cl^- and large anions inside the neuron contribute negative charges.
- The opposing Na^+ and K^+ gradients are maintained by ATP-requiring **sodium-potassium pumps** that continuously transport three Na^+ out of the neuron for every two K^+ transported in.

5 Compare a graded potential with an action potential, describing the production and transmission of each.

- If a stimulus causes the membrane potential to become less negative, the membrane becomes **depolarized**. If the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized**.
- A **graded potential** is a local response that varies in magnitude depending on the strength of the applied stimulus. A graded potential fades out within a few millimeters of its point of origin.
- If voltage across the membrane decreases to a critical **threshold level**, **voltage-activated ion channels** open, allowing Na^+ to flow into the neuron, and an **action potential** is generated. The action potential is a *wave of depolarization* that moves down the axon.
- As the action potential moves down the axon, **repolarization** occurs behind it. During depolarization, the axon enters an **absolute refractory period**, a time when it cannot transmit another action potential. When enough gates controlling Na^+ channels have been reset, the neuron enters a *relative refractory period*, a time when the threshold to fire the neuron is higher.

- The action potential is an **all-or-none response**; no variation exists in the strength of a single impulse. Either the membrane potential exceeds threshold level, leading to transmission of an action potential, or it does not. Once begun, an action potential is self-propagating.

6 Contrast continuous conduction with saltatory conduction.

- *Continuous conduction*, which involves the entire axon plasma membrane, takes place in unmyelinated neurons.
- **Saltatory conduction**, which is more rapid and requires less energy than continuous conduction, takes place in myelinated neurons. Depolarization appears to leap along the axon from one node of Ranvier to the next.

41.4 Transmitting Information across Synapses

(page 872)

7 Describe the actions of the neurotransmitters identified in this chapter.

- The junction between two neurons or between a neuron and effector is a **synapse**. Most synapses are chemical. In synaptic transmission a **presynaptic neuron** releases a neurotransmitter, a chemical messenger, from its *synaptic vesicles*.
- **Acetylcholine** is a neurotransmitter that triggers contraction of skeletal muscle.
- The **biogenic amines**, which include **norepinephrine**, **serotonin**, and **dopamine**, have multiple functions. They play important roles in regulating mood. Dopamine is also important in motor function.
- Several amino acids function as neurotransmitters, including **glutamate**, the main excitatory neurotransmitter in the brain, and **GABA**, a widespread inhibitory neurotransmitter.
- The neuropeptides, which are opioids, include the **endorphins** (e.g., *beta-endorphin*) and the **enkephalins**.
- **Nitric oxide (NO)**, a gaseous neurotransmitter, transmits signals from postsynaptic neurons to presynaptic neurons, the opposite direction from other neurotransmitters.

8 List the sequence of events that take place in synaptic transmission and draw diagrams to support your description.

- Calcium ions induce synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter into the **synaptic cleft**. The neurotransmitter diffuses across the

synaptic cleft and combines with specific receptors on a postsynaptic neuron (see Fig. 41-11b).

- Many neurotransmitter receptors are proteins that form **ligand-gated channels**. Others activate a G protein and work through a **second messenger** such as **cAMP**.

9 Compare excitatory and inhibitory signals and their effects.

- Binding of a neurotransmitter to a receptor can cause either an **excitatory postsynaptic potential (EPSP)** or an **inhibitory postsynaptic potential (IPSP)**, depending on the type of receptor. EPSPs bring the neuron closer to firing. IPSPs move the neuron farther away from its firing level.

41.5 Neural Integration (page 877)

10 Define neural integration and describe how a postsynaptic neuron sums incoming stimuli and “decides” whether to fire.

- Neural **integration** is the process of summing, or integrating, incoming signals.
- Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. **Summation** is the process of adding and subtracting incoming signals. By summation of several EPSPs, the neuron may be brought to the critical firing level.
- **Temporal summation** occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. **Spatial summation** occurs when several closely spaced synaptic terminals release neurotransmitter simultaneously, stimulating the postsynaptic neuron at several different places.

41.6 Neural Circuits: Complex Information Signaling (page 877)

11 Distinguish between convergence and divergence, and explain why each is important to the functioning of neural circuits.

- Complex **neural circuits** are possible because of associations such as convergence and divergence. In **convergence** a single neuron is affected by signals from two or more presynaptic neurons. Convergence allows the CNS to integrate incoming information from various sources. In **divergence** a single presynaptic neuron stimulates many postsynaptic neurons, allowing widespread effect.

Test Your Understanding

Know and Comprehend

- Summing incoming neural signals is part of (a) reception (b) transmission (c) integration (d) action by effectors (e) afferent neuron transmission
- The myelin sheath is produced around axons in the PNS by (a) ganglia (b) neuron cell bodies (c) dendrites (d) Schwann cells (e) oligodendrocytes
- Which of the following occurs first when voltage reaches the threshold level in a neuron plasma membrane? (a) voltage-activated Na^+ channels open (b) K^+ channels open (c) the membrane hyperpolarizes (d) neurotransmitter is released (e) K^+ channels close
- Saltatory conduction (a) requires more energy than continuous conduction (b) occurs in unmyelinated neurons (c) occurs when the action potential jumps from one node of Ranvier to the next (d) slows transmission of an impulse (e) depends on the action of GABA
- Receptors for serotonin and many other neurotransmitters (a) are voltage-activated ion channels (b) permit influx of chloride ions, leading to depolarization (c) inhibit EPSPs (d) are ligand-gated channels (e) are passive ion channels
- A presynaptic neuron in the cerebrum transmits information to hundreds of other neurons. This process is an example of (a) convergence (b) divergence (c) temporal summation (d) spatial summation (e) a graded potential

Apply and Analyze

7. **VISUALIZE** Describe the action taking place at each of the numbered steps in the figure.

8. **VISUALIZE** Using the diagram in question 7, add several red spheres in the synaptic cleft to represent molecules of an antidepressant medication. Illustrate a potential mechanism of action for the antidepressant molecules. (Extend the diagram if you like.)

9. **INTERPRET DATA** State whether each of the following would result in an EPSP or IPSP (explain your answer). (a) Na^{+} enter postsynaptic neuron (b) K^{+} diffuse out of postsynaptic neuron (c) Cl^{-} enter postsynaptic neuron.

Evaluate and Synthesize

10. Develop a hypothesis to explain why acetylcholine has an excitatory effect on skeletal muscle but an inhibitory effect on cardiac muscle.
11. **SCIENCE, TECHNOLOGY, AND SOCIETY** A test for risk of Alzheimer's disease is available. Based on gene markers that can be identified in a saliva sample, a healthy person can learn his or her approximate risk for AD. How might this information be useful to people? Would you be concerned about the psychological consequences of a person knowing that he or she has a high risk of AD? Would you want to know?
12. **SCIENCE, TECHNOLOGY, AND SOCIETY** Investigators have genetically engineered cells to produce acetylcholine, dopamine, GABA, and other neurotransmitters. In what ways might these cells be useful in neurobiological research? How might they be useful in clinical medicine?
13. **EVOLUTION LINK** From the perspective of adaptation, hypothesize the advantages of neural circuits characterized by a great deal of convergence and divergence.

42 Neural Regulation

KEY CONCEPTS

- 42.1** The trend in the evolution of invertebrate nervous systems is toward greater complexity, with increased number and concentration of neurons and greater specialization of function.
- 42.2** The vertebrate nervous system consists of a central nervous system (CNS), which includes the brain and spinal cord, and a peripheral nervous system (PNS), which includes sensory receptors and nerves.
- 42.3** During the evolution of the vertebrate brain, the cerebrum and cerebellum have become larger and more complex.
- 42.4** The CNS receives sensory information from both the internal and external environments, integrates it, and determines appropriate responses. The association areas of the brain are responsible for learning, memory, language, thought, and judgment.
- 42.5** The PNS has two divisions. The somatic division transmits information between the external environment and the CNS. The autonomic division transmits information between the internal environment and the CNS.
- 42.6** Many prescribed and illicit drugs affect mood by affecting neurotransmitter concentrations in the brain.

A frog flicks out its tongue with lightning speed to capture a fly, a rabbit escapes from a predator, and you learn biology, perhaps not that quickly. In a complex nervous system, millions of neurons work together to transmit information from the external environment to the central nervous system (CNS). After the information is integrated, neural signals are transmitted to the effectors that can produce effective responses.

The nervous system also regulates heart rate, breathing, and hundreds of other internal activities. Nerves must transmit information from all the organs in the body to the CNS. Then, other nerves transmit back the information that will allow organs to make the adjustments necessary to maintain homeostasis. Researchers have focused extensively on just how neurons interact. However, we are only beginning to understand the mechanisms that propel the many vital functions of the nervous system.

Neurobiologists use a variety of methods to study the mechanisms of neural function. For example, improved imaging methods, including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), have provided investigators with a window through which to observe brain activity (see photograph).

PHOTO: Brain activation during hearing. Colored positron emission tomography (PET) scan data, showing brain activity (colored) from hearing a known language. The PET data has been laid over three-dimensional magnetic resonance imaging (MRI) scans of profiles of the left (in the brain shown on the *left*) and right (in the brain on the *right*) brain hemispheres. The front of the brain (frontal lobe) is positioned at the far left and right. The *red* and *green* areas visible in the temporal lobe of the brain are auditory areas. The *yellow* area (in the left temporal lobe) recognizes known words. The *pink* area (in the left frontal lobe) is Broca's area, which controls the ability to speak. Zephyr/Science Source

These methods permit investigators to study the responses of neural networks in the brain while an individual is performing a task, such as hearing. When performing a task, neurons in the area of the brain involved become active and consume more oxygen. The flow of oxygen-rich blood increases to that area. PET and fMRI detect changes that take place in response to a very brief stimulus.

In this chapter we compare several types of nervous systems. We then examine the structure and function of the vertebrate nervous system, with emphasis on the function of the human brain. We explore some of the frontiers of neurobiology, such as mechanisms involved in information processing and drug addiction.

42.1 Invertebrate Nervous Systems: Trends in Evolution

LEARNING OBJECTIVES

- 1 Contrast nerve nets and radial nervous systems with bilateral nervous systems.
- 2 Identify trends in the evolution of invertebrate nervous systems.

An animal's lifestyle is closely related to the organization and complexity of its nervous system. *Hydra* and other cnidarians have a **nerve net** consisting of interconnected neurons with no central control organ. Sensory cells are located in the epidermis, and the cnidarian can respond to stimuli from any direction (see Chapter 31). When a neuron is stimulated, electrical signals are sent from neuron to neuron in all directions (FIG. 42-1). Responses may involve large parts of the body.

An advantage of the nerve net is that the cnidarian responds effectively to predator or prey approaching from any direction. *Hydra* responds by discharging nematocysts (stinging structures) and coordinating the movements of its tentacles to capture food. Some cnidarians have two or more nerve nets. In some jellyfish a slow-transmission nerve net coordinates movement of the tentacles, and a second nerve net, which is faster, coordinates swimming.

The *radial nervous system* of the sea star and other echinoderms is a modified nerve net. This system shows some degree of selective organization of neurons into more than a diffuse network. It consists of a nerve ring around the mouth, from which a large radial nerve extends into each arm. Branches of these nerves, which form a network somewhat similar to the nerve net of *Hydra*, coordinate the animal's movement.

Figure 42-1 *Hydra's* nerve net
Hydra and other cnidarians have a network of neurons with no central control organ.

Bilaterally symmetrical animals have a *bilateral nervous system*. In planarian flatworms the head region contains concentrations of nerve cells called **cerebral ganglia** (FIG. 42-2). These ganglia serve as a primitive brain and have some control over the rest of the nervous system. Typically, two solid, ventral, longitudinal *nerve cords* extend from the ganglia to the posterior end of the body. A **nerve cord** is a bundle of nerves that extends from a central ganglion (or brain) and gives rise to smaller nerves. In planaria, transverse nerves connect the two nerve cords and connect the brain with the eyespots. This arrangement is called a "ladder-type" nervous system.

Annelids and arthropods typically have a solid ventral nerve cord (FIG. 42-3). The cell bodies of many of the neurons are massed into **ganglia**. Afferent and efferent neurons lie in lateral nerves that link the ganglia with muscles and other body structures. If an earthworm's brain is removed, the animal can move almost as well as before. However, when it bumps into an obstacle, it persists in a futile effort to move forward rather than turn aside. To respond adaptively to environmental change, the earthworm needs its brain.

The cerebral ganglia of some arthropods differ from those of annelids in that they have specific functional regions. These areas are specialized for integrating information transmitted to the ganglia from sense organs.

Mollusks with inactive lifestyles have relatively simple nervous systems with little cephalization and very simple sense organs. Typically, there are two nerve cords; one extends down each side of the body. Several pairs of ganglia are located along the cords.

The cephalopod mollusks (squids and octopods) have complex nervous systems that include well-developed sense organs. The cephalopod nervous system is adapted to the active, predatory lifestyle of these animals. Neurons

Figure 42-2 Ladder-type nervous system of flatworms
Cerebral ganglia in the head region serve as a simple brain. The longitudinal nerve cords are connected by transverse nerves.

(a) Earthworm nervous system. Annelids have a dorsal anterior brain and one or more ventral nerve cords. Cell bodies of the neurons are located in ganglia that are connected by the ventral nerve cord.

(b) Insect nervous system. The arthropod brain is continuous with the ventral nerve cord. The brain is more specialized than in annelids.

Figure 42-3 The annelid and arthropod nervous systems

concentrated in ganglia are massed in a ring surrounding the esophagus; they make up a brain that contains about 168 million nerve cells. Like the vertebrate brain, the cephalopod brain has lobes and intricate folds, and particular areas are specialized as centers for specific functions. The octopus is capable of considerable learning and can be taught difficult tasks. In fact, cephalopods are considered the most intelligent invertebrates.

We can identify the following trends in the evolution of nervous systems:

1. **Increased number of nerve cells.**
2. **Concentration of nerve cells.** The nerve cells form masses of tissue that become *ganglia* (concentrations of nerve cell bodies) and *brain*, and they form thick cords of tissue that become *nerve cords* and *nerves*.
3. **Specialization of function.** For example, transmission of nerve impulses in one direction requires both **afferent nerves**, which conduct impulses toward a central nervous system (CNS), and **efferent nerves**, which transmit

impulses away from the CNS to the **effectors** (muscles and glands). Certain parts of the CNS become specialized to perform specific functions, and distinct structural and functional regions can be identified.

4. **Increased number of interneurons and more complex synaptic contacts.** These contacts permit greater integration of incoming messages, provide a greater range of responses, and allow more precise responses.
5. **Cephalization, or formation of a head.** A bilaterally symmetrical animal generally moves in a forward direction. Concentration of sense organs at the front end of the body lets the animal detect an enemy quickly enough to escape or to see, hear, or smell food in time to capture it. Response can be rapid if short pathways link sense organs to decision-making nerve cells nearby. Therefore, nerve cells are typically concentrated in the head region and organized to form ganglia or a **brain**.

CHECKPOINT 42.1

- Contrast the nervous system of the insect with that of the flatworm.
- What are some trends in the evolution of nervous systems?
- What are some advantages of cephalization?

42.2 Overview of the Vertebrate Nervous System

LEARNING OBJECTIVE

- 3 Describe the two main divisions of the vertebrate nervous system and summarize their functions.

An animal's range of possible responses depends in large part on how many neurons it has and how they are organized in the nervous system. Some invertebrate nervous systems have only a few hundred neurons. As animal groups evolved, nervous systems became increasingly complex. A common roundworm has 302 neurons. Elephant, whale, and human brains have billions. How neurons are organized is critical in determining learning ability and flexibility of behavior.

The vertebrate nervous system has two main divisions: the **central nervous system (CNS)** and the **peripheral nervous system (PNS)** (FIG. 42-4). The CNS consists of a highly developed brain that is continuous with the dorsal, tubular nerve cord, or **spinal cord**. Serving as central control, these organs integrate incoming information and determine appropriate responses.

The PNS is made up of the sensory receptors (e.g., tactile, auditory, and visual receptors) and the nerves, which are the communication lines. Various parts of the body are linked to the CNS by cranial nerves and by spinal nerves. Afferent (sensory) neurons in these nerves continuously inform the CNS of changing conditions. Then efferent neurons transmit the “decisions” of the CNS to appropriate muscles and glands, which make the adjustments needed to maintain homeostasis.

Figure 42-4 Organization of the vertebrate nervous system
The two main divisions of the vertebrate nervous system are the central nervous system (CNS) and the peripheral nervous system (PNS).

For convenience, the PNS is subdivided into *somatic* and *autonomic divisions*. Most of the receptors and nerves concerned with changes in the external environment are somatic. Those that regulate the internal environment are autonomic. Both divisions have afferent nerves, which transmit messages from sensory receptors to the CNS, and efferent nerves, which transmit information back from the CNS to the structures that respond. The autonomic division has two kinds of efferent pathways: sympathetic and parasympathetic nerves (discussed later in the chapter).

CHECKPOINT 42.2

- **VISUALIZE** Draw a diagram showing the main components of the CNS and the main components of the PNS.
- Describe the functions of each component of the CNS and PNS.

42.3 Evolution of the Vertebrate Brain

LEARNING OBJECTIVE

- 4 Trace the development of the principal vertebrate brain regions from the hindbrain, midbrain, and forebrain, and compare the brains of fishes, amphibians, reptiles, birds, and mammals.

All vertebrates, from fishes to mammals, have the same basic brain structure; different parts of the brain are specialized in the various vertebrate classes. The evolutionary trend is toward increasing complexity, especially of the cerebrum and cerebellum.

In the early vertebrate embryo, the brain and spinal cord differentiate from a single tube of tissue, the **neural tube**. Anteriorly, the tube expands and develops into the brain. Posteriorly, the tube becomes the spinal cord. Brain and spinal

cord remain continuous, and their cavities communicate. As the brain begins to differentiate, three bulges become visible: the hindbrain, midbrain, and forebrain (FIG. 42-5).

The hindbrain develops into the medulla, pons, and cerebellum

As indicated in TABLE 42-1, the hindbrain subdivides to form the metencephalon, which gives rise to the cerebellum and pons, and the myelencephalon, which gives rise to the medulla. The medulla, pons, and midbrain make up the brain stem, the elongated portion of the brain that looks like a stalk holding up the cerebrum.

The medulla, the most posterior part of the brain, is continuous with the spinal cord. Its cavity, the fourth ventricle, is continuous with the central canal of the spinal cord and with a channel that runs through the midbrain. The fourth ventricle is one of four interconnected chambers in the brain through which cerebrospinal fluid flows. The walls of the medulla are thick and made up largely of nerve tracts (bundles of axons) that connect the spinal cord with various parts of the brain. The medulla contains centers that regulate life-sustaining functions such as respiration, heartbeat, and blood pressure. Other reflex centers in the medulla regulate activities such as swallowing, coughing, and vomiting.

The cerebellum is responsible for muscle tone, posture, and equilibrium. It also refines and coordinates muscle activity. In humans the cerebellum provides input to motor areas in the cerebral cortex, and in this way it helps plan and initiate voluntary activity. Certain regions of the cerebellum store implicit memories (unconscious memories for perceptual and motor skills, such as swimming and skating).

The size and shape of the cerebellum vary among the vertebrate classes (FIG. 42-6). Development of the cerebellum is roughly correlated with the extent and complexity of muscular activity, reflecting the principle that the relative size of a brain part correlates with its importance to the behavior of the species. The cerebellum is not well developed in jawless fishes, amphibians, and non-avian reptiles. In jawed fishes, birds, and mammals, the cerebellum is large and well developed.

Injury or removal of the cerebellum results in impaired muscle coordination. A bird without a cerebellum cannot fly, and its

Figure 42-5 Early development of the vertebrate nervous system

Early in the development of the vertebrate embryo, the anterior end of the neural tube differentiates into the hindbrain, midbrain, and forebrain. These primary divisions subdivide and eventually give rise to specific structures of the adult brain.

wings thrash about jerkily. When the human cerebellum is injured by a blow or by disease, muscular movements are uncoordinated. Any activity requiring delicate coordination, such as typing a text on your cell phone, becomes very difficult if not impossible.

In mammals the pons contains a thick bundle of fibers that transmits information between the two sides of the cerebellum. The pons also serves as a bridge that connects the medulla and cerebellum with other regions of the brain. The pons contains centers that help regulate respiration and nuclei that relay impulses from the cerebrum to the cerebellum. Recall from Chapter 41 that a nucleus is a group of cell bodies within the CNS.

The midbrain is prominent in fishes and amphibians

In fishes and amphibians, the midbrain, or mesencephalon, is the most prominent part of the brain and serves as the main association area. It receives incoming sensory information, integrates it, and sends decisions to appropriate motor nerves. The dorsal portion of the midbrain is differentiated to some extent. For example, the optic lobes are specialized for visual interpretations.

Table 42-1 Differentiation of CNS Structures			
Early Embryonic Divisions	Subdivisions	Derivatives in Adult	Cavity
BRAIN			
Forebrain	Telencephalon	Cerebrum	Lateral ventricles (first and second ventricles)
	Diencephalon	Thalamus, hypothalamus, epiphysis (pineal body)	Third ventricle
Midbrain	Mesencephalon	Optic lobes in fish and amphibians; superior and inferior colliculi in mammals	Cerebral aqueduct
Hindbrain	Metencephalon	Cerebellum, pons	
	Myelencephalon	Medulla	Fourth ventricle
SPINAL CORD		Spinal cord	Central canal

Key Point

Although different parts of the brain are specialized in various vertebrate groups, there is an evolutionary trend toward larger size and greater complexity of the cerebrum and cerebellum.

In reptiles (including birds) and mammals, many functions of the optic lobes are assumed by the cerebrum, which develops from the forebrain. In mammals the midbrain consists of the *superior colliculi*, centers for visual reflexes such as pupil constriction, and the *inferior colliculi*, centers for certain auditory reflexes. The inferior colliculi are major integration centers for incoming auditory information. The mammalian midbrain also contains a center (the *red nucleus*) that helps maintain muscle tone and posture.

The forebrain gives rise to the thalamus, hypothalamus, and cerebrum

The **forebrain** subdivides to form the *telencephalon* and *diencephalon*. The *diencephalon* gives rise to the thalamus and hypothalamus.

In all vertebrate classes, the **thalamus** is a relay center for motor and sensory messages. In mammals all sensory messages except those from the olfactory receptors are delivered to the thalamus, where they are integrated before they are relayed to the sensory areas of the cerebrum.

The **hypothalamus**, which lies below the thalamus, forms the floor of the third ventricle. The hypothalamus is a major coordinating center for regulating autonomic and somatic responses. It integrates incoming information and provides input to centers in the medulla and spinal cord that regulate activities such as heart rate, respiration, and digestive system function. In birds and mammals, the hypothalamus controls body temperature. It also contains olfactory centers, regulates appetite and water balance, and is important in emotional and sexual responses. As we discuss in Chapter 49, the hypothalamus links the nervous and endocrine systems and produces certain hormones.

The *telencephalon* gives rise to the **cerebrum**. The *lateral ventricles* (also called the first and second ventricles) lie within the cerebrum. Each lateral ventricle connects with the third ventricle (within the diencephalon) by way of a channel. In most vertebrate groups, the telencephalon also gives rise to the **olfactory bulbs**. These structures are important in the chemical sense of smell, which is the dominant sense in most aquatic and terrestrial vertebrates. In fact, much of brain development in vertebrates appears to focus on integrating olfactory information.

Figure 42-6 Evolution of the vertebrate brain

Comparison of the brains of members of six vertebrate groups reveals basic similarities and evolutionary trends. (Brains are not drawn to scale.) Note that different parts of the brain are specialized in the various groups. The large olfactory lobes in the shark brain (a) are essential to this predator's highly developed sense of smell. (b–f) During the course of evolution, the cerebrum and cerebellum have become larger and more complex. In mammals (f), the cerebrum is the most prominent part of the brain; the cerebral cortex, the thin outer layer of the cerebrum, is highly convoluted (folded), which greatly increases its surface area. The diencephalon and part of the brain stem are covered by the large cerebrum.

PREDICT Imagine that humans continue to thrive during the next several thousand years. Predict evolutionary changes that might occur in the human brain.

In fishes and amphibians, a large part of the cerebrum is devoted to this function. In birds, centers in the cerebrum control eating, flying, singing, and other action patterns.

In most vertebrates the cerebrum is divided into right and left *cerebral hemispheres*. Most of the cerebrum is made of **white matter**, which consists mainly of myelinated axons that connect various parts of the brain. In mammals and in the majority of reptiles, the **cerebral cortex** makes up the outer portion of the cerebrum. The cerebral cortex is composed of **gray matter**, which consists of cell bodies, dendrites, and unmyelinated axons.

Certain reptiles and all mammals have a type of cerebral cortex called the *neocortex*. Most of the neocortex consists of *association areas*, regions that link sensory and motor functions and that are responsible for higher functions, such as learning and reasoning. The neocortex is very extensive in mammals, making up the bulk of the cerebrum. In humans most of the cerebral cortex is neocortex that consists of six distinct cell layers. Part of the limbic system (discussed later in this chapter) has only three layers. This region is referred to as the *paleocortex* (ancient cortex).

In mammals the cerebrum is the most prominent part of the brain. During embryonic development, it expands and grows backward, covering many other brain structures. The surface area of the human cerebral cortex is greatly expanded by numerous folds called **convolutions**. The furrows between them are called **sulci** (sing., *sulcus*) if shallow and **fissures** if deep. In mammals the cerebrum is responsible for numerous functions performed by other parts of the brain in other vertebrates. In addition, the mammalian cerebrum has highly developed association functions.

- What structures are derived from the vertebrate embryonic forebrain? the hindbrain? What are the functions of these structures?
- Compare the brain of a mammal with the brain of an amphibian.

42.4 The Human Central Nervous System

LEARNING OBJECTIVES

- 5 Describe the structure and functions of the human spinal cord.
- 6 Describe the structure and functions of the human cerebrum.
- 7 Summarize the sleep–wake cycle and contrast rapid eye movement (REM) sleep with non-REM sleep.
- 8 Describe the actions of the limbic system; include the role of the amygdala in emotional expression and in response to danger.
- 9 Summarize how the brain processes information; include a description of synaptic plasticity and the neurobiological changes that take place during learning.

The soft, fragile human brain consists of billions of neurons that are connected by trillions of synapses. This 3-pound mass of tissue perceives and processes information and determines effective responses more capably and efficiently than the most sophisticated computer.

The brain and spinal cord are well protected. Encased within bone, they are covered by three layers of connective tissue, collectively called the **meninges**. The three meningeal layers are the tough, outer **dura mater**; the middle **arachnoid**; and the thin, vascular **pia mater**, which adheres closely to the tissue of the brain and spinal cord (**FIG. 42-7**). *Meningitis* is a disease in which these coverings become infected and inflamed.

The space between the arachnoid and the pia mater is the subarachnoid space, which contains **cerebrospinal fluid (CSF)**. This shock-absorbing fluid cushions the brain and spinal cord against mechanical injury. It also serves as a medium for exchange of nutrients and waste products between the blood and brain. CSF is produced by special networks of capillaries, collectively called the *choroid plexus*, which extend from the pia mater into the ventricles. After circulating through the ventricles, CSF passes into the subarachnoid space. It is then reabsorbed into large blood sinuses within the dura mater.

The spinal cord transmits impulses to and from the brain

The tubular **spinal cord** extends from the base of the brain to the level of the second lumbar vertebra. A cross-section view through the spinal cord reveals a small *central canal* surrounded by an area of gray matter shaped a bit like the letter H (**FIG. 42-8**). The gray matter consists of large masses of cell bodies, dendrites, unmyelinated axons, and glial cells.

The white matter, found outside the gray matter, consists of myelinated axons arranged in bundles called *tracts* or *pathways*. *Ascending tracts* conduct impulses up the cord to the brain. For example, the spinothalamic tracts in the anterior and lateral columns of the white matter conduct pain and temperature information from sensory neurons in the skin. The pyramidal tracts are *descending tracts* that convey impulses from the cerebrum to motor nerves at various levels in the cord. We describe the spinal nerves later in this chapter.

In addition to transmitting impulses to and from the brain, the spinal cord controls many reflex activities. A **reflex action** is a relatively simple, involuntary motor response to a stimulus. Although most reflex actions are more complex, let us consider a *withdrawal reflex*, in which a neural circuit consisting of three types of neurons carries out a response to a stimulus (**FIG. 42-9**). Suppose that your hand accidentally touches a flame. Almost instantly, and even before you become consciously aware of what has happened, you jerk your hand away.

The instant your skin contacts the flame, a sensory neuron transmits a message from pain receptors in the skin to the spinal cord. Within the spinal cord, a sensory neuron transmits the signal to an interneuron. The interneuron integrates the information and signals an appropriate efferent (motor) neuron, which conducts the information to groups of muscles. The muscles respond by contracting, jerking the hand away from the flame.

(a) Frontal section through the superior part of the brain. Note the dural sinus, a blood sinus, between two layers of the dura mater. Blood leaving the brain flows into such sinuses and then circulates to the large jugular veins in the neck.

(b) Sagittal section through the brain. The CSF, which cushions the brain and spinal cord, is produced by the choroid plexi in the walls of the ventricles. This fluid circulates through the ventricles and subarachnoid space. It is continuously produced and then reabsorbed into the blood of the dural sinuses.

Figure 42-7 Protection of the brain and spinal cord

The CNS is well protected by the skull and meninges and by cerebrospinal fluid (CSF).

Actually, many neurons in sensory, association, and motor nerves participate in such a reflex action. Generally, we are not even consciously aware that all these responding muscles exist. In summary, signals are transmitted through a withdrawal reflex in the following sequence:

reception by sensory receptor in skin → sensory neuron transmits signal to CNS → interneuron in CNS integrates information → efferent (motor) neuron transmits signal to muscle → muscle contracts

At the same time that the reflex pathway is activated, a message is sent up the spinal cord to the conscious areas of the brain. As you pull your hand away from the flame, you become aware of what has happened and feel the pain. This awareness, however, is not part of the reflex response.

The spinal cord has some plasticity and is capable of training. For example, sensory feedback from exercise increases the strength of neural connections in the spinal cord. Approximately 300,000 people in the United

States are living with spinal cord injury.¹ The leading cause of these injuries is motor vehicle crashes. When descending connections with the brain are intact, some victims of spinal cord injury can develop at least some limited ability to walk again.

The most prominent part of the human brain is the cerebrum

The structure and functions of the main parts of the human brain are summarized in **TABLE 42-2**, and major regions of the brain are illustrated in **FIGURE 42-10** on page 892 and **FIGURE 42-11** on page 893. As in other mammals, the human cerebral cortex consists of right and left *cerebral hemispheres*.

Specific areas of the cerebrum are specialized for performing specific functions The cerebral cortex is functionally divided into three areas: (1) *sensory areas* receive incoming signals from the sense organs; (2) *motor areas* control voluntary movement; and (3) **association areas** link the sensory and motor areas and are responsible for thought, learning, language, memory, judgment, decision making, and personality. You can see positron-emission tomography (PET) scans showing some functional areas of the cerebrum in **FIGURE 42-12** on page 894.

Investigators have mapped the cerebral cortex, locating the areas responsible for different functions. The **occipital lobes** contain the visual centers. Stimulation of these areas, even by a blow on the back of the head, causes the sensation of light; their removal

causes blindness. The centers for hearing are located in the **temporal lobes** of the brain above the ear; stimulation by a blow causes a sensation of noise. Removal of both auditory areas causes deafness. Removal of one does not cause deafness in one ear; instead, it produces a decrease in the auditory acuity of both ears. Association areas in the temporal lobes help us identify incoming sound stimuli.

A groove called the *central sulcus* crosses the top of each hemisphere from medial to lateral edge. This groove partially

Figure 42-9 Withdrawal reflex

A reflex action is a coordinated, involuntary motor response to a stimulus.

Table 42-2 The Human Brain

Structure	Description	Function
BRAIN STEM		
Medulla	Continuous with spinal cord; primarily made up of nerves passing from spinal cord to rest of brain	Contains vital centers (clusters of neuron cell bodies) that control heartbeat, respiration, and blood pressure; contains centers that control swallowing, coughing, and vomiting
Pons	Forms bulge on anterior surface of brain stem	Connects various parts of brain with one another; contains respiratory and sleep centers
Midbrain	Just above pons	Center for visual and auditory reflexes (e.g., pupil reflex, blinking, and adjusting ear to volume of sound)
THALAMUS	At top of brain stem	Main sensory relay center for conducting information between spinal cord and cerebrum; neurons in thalamus sort and interpret all incoming sensory information (except olfaction) before relaying messages to appropriate neurons in cerebrum
HYPOTHALAMUS	Just below thalamus; pituitary gland is connected to hypothalamus by stalk of neural tissue	Contains centers for control of body temperature, appetite, and fat metabolism; regulates pituitary gland; important in emotional and sexual responses, and in sleep–wake cycle
CEREBELLUM	Second-largest division of brain	Muscle coordination and refinement of movements; muscle tone, posture, and equilibrium; helps plan and initiate voluntary activity; stores implicit memories
CEREBRUM	Largest, most prominent part of human brain; longitudinal fissure divides cerebrum into right and left hemispheres, each divided into frontal, parietal, temporal, and occipital lobes	Center of intellect, memory, judgment, consciousness, and language; also controls sensation and motor functions
Cerebral cortex (outer gray matter)	Arranged into convolutions (folds) that increase surface area; functionally, cerebral cortex is divided into: 1. Motor areas 2. Sensory areas 3. Association areas	1. Control movement of voluntary muscles 2. Receive incoming information from eyes, ears, touch receptors, and other sensory receptors 3. Centers for intellect, memory, language, and emotion; interpret incoming sensory information
White matter	Consists of myelinated axons of neurons that connect various regions of brain; axons are arranged in bundles (tracts)	Connects the following: 1. Neurons within same hemisphere 2. Right and left hemispheres 3. Cerebrum with other parts of brain and spinal cord

separates the **frontal lobes** from the **parietal lobes**. The frontal lobes have important motor and association areas. The **prefrontal cortex** is an association area in each frontal lobe that is crucial in evaluating information, making decisions, planning, organizing responses, and interpreting incoming sensory information. The *motor areas* in the frontal lobes control the skeletal muscles. The *somatosensory area* in the anterior region of the parietal lobes receives information regarding touch, pressure, heat, cold, and pain from sense organs in the skin. This region also receives information regarding position of the body. Association areas in the parietal lobes are important in helping us pay attention to such incoming information.

The size of the motor area in the brain for any given part of the body is proportional to the complexity of movement involved, not to the amount of muscle. Predictably, areas that control the hands and face are relatively large (FIG. 42-13 on page 895). A similar relationship exists between the sensory area and the sensitivity of the region of the skin from which it receives impulses. These relationships are visually represented

as the sensory homunculus (“little person”) and the motor homunculus in Figure 42-13.

Neural fibers in the brain cross so that one side of the brain controls the opposite side of the body. Also, as can be seen in Figure 42-13b, the uppermost part of the cortex controls the lower limbs of the body.

When all the areas of known function are plotted, they cover almost all the rat’s cortex, a large part of the dog’s, a moderate amount of the monkey’s, and only a small part of the total surface of the human cortex. The remaining cortical areas are association areas. Somehow the association regions integrate the diverse impulses reaching the brain so that an appropriate response is made. When disease or accident destroys the functioning of one or more association areas, the ability to recognize certain kinds of symbols may be lost. For example, the names of objects may be forgotten, although their functions are remembered and understood.

The two cerebral hemispheres are specialized for certain functions. As will be discussed later in this chapter, the left hemisphere is specialized for language functions. This part of the

Figure 42-10 The human brain

Human brain, lateral view. Each cerebral hemisphere is divided into four major lobes. The diencephalon and part of the brain stem are covered by the cerebrum. Compare the diagram (a) with the photograph of a human brain (b).

brain is also specialized for logical decision making and retrieval of facts. The right hemisphere is specialized for emotional processing and for visual-spatial tasks such as recognizing faces.

Axons in the white matter of the cerebrum connect parts of the brain

The white matter of the cerebrum lies beneath the cerebral cortex. Nerve fibers of the white matter connect the cortical areas with one another and with other parts of the nervous system (see Table 42-2). A large band of white matter, the **corpus callosum**, connects the right and left hemispheres (see Fig. 42-11).

Deep within the white matter of the cerebrum lie the *basal ganglia*, paired groups of nuclei (gray matter). These nuclei play an important role in coordinating movement. The basal ganglia send signals to and receive signals from the *substantia nigra* in the midbrain. Neurons from the substantia nigra that project (extend) to the basal ganglia produce **dopamine**, a neurotransmitter that helps balance inhibition and excitation of neurons involved in motor function. (See the discussion of neurotransmitters in Chapter 41.) Other neurons from the substantia nigra signal nuclei in the thalamus, which in turn relay information to the motor cortex. Neurons from the substantia nigra that signal the thalamus release the neurotransmitter

gamma-aminobutyric acid (GABA). Just how these areas work together to coordinate motor function is not yet fully understood.

Nearly one million people in the United States alone are affected by Parkinson's disease, a progressive neurological disorder that affects movement. In this disease dopamine-producing neurons die over time, decreasing the available dopamine. This decrease causes a progressive decrease in effective neural messages regarding motor responses. The resulting symptoms include tremors in the limbs and face, a slowing of movement, poor muscle coordination, and impaired walking and balance. Several medications, including a dopamine precursor (l-DOPA), are used to treat symptoms of the disorder.

The body follows a circadian rhythm of sleep and wakefulness

Researchers have determined that many animals, including nematodes and fruit flies, sleep. Predators typically sleep for longer periods than animals that are preyed upon. For example, rabbits sleep only for a few minutes at a time. In some birds and aquatic mammals, one cerebral hemisphere sleeps at a time, allowing the animal to remain aware of its environment. Sleeping with one hemisphere permits eared seals and whales to move to the surface to breathe without awakening.

Figure 42-11 Midsagittal section through the human brain

Half of the brain has been cut away, exposing structures normally covered by the cerebrum. Compare the diagram (a) with the photograph of a human brain (b).

Humans and many other animals follow a 24-hour **circadian** (daily) rhythm of sleeping and then being awake. When we are awake, we are typically aware of the external world and of ourselves, including our thoughts, perceptions, and emotions. In contrast, when we are asleep, the body receives messages from the environment, but we are not aware of them.

The **suprachiasmatic nucleus**, the most important of the body's biological clocks, is located in the hypothalamus. The suprachiasmatic nucleus receives information about the duration of light and dark from the retina of the eye and transmits information to other nuclei and neurons. The suprachiasmatic nucleus signals the **pineal gland** about light and dark. This endocrine gland is located in the midline of the diencephalon.

The pineal gland produces **melatonin**, a hormone that plays a role in regulating the sleep-wake cycle. The pineal gland secretes up to 10 times as much melatonin during darkness as during daylight. *Jet lag*, the state of fatigue and decreased physical and mental performance we experience when we fly to a different time zone, occurs because the body is no longer synchronized with its light-dark cycle. Some individuals take melatonin supplements to promote sleep, but their effectiveness has not been proven.

The hypothalamus, thalamus, and brain stem are all involved in regulating the sleep-wake cycle. Neurons in these regions secrete several neurotransmitters important in regulating sleep, including acetylcholine, norepinephrine, and serotonin. The **reticular activating system (RAS)** is a neural pathway within the brain stem and thalamus. The RAS receives messages from neurons in the spinal cord and from many other parts of the nervous system, and it communicates with the cerebral cortex by complex neural circuits. When certain neurons of the RAS bombard the cerebral cortex with stimuli, an individual feels alert and can focus on specific thoughts. If the RAS is severely damaged, the person may pass into a deep, permanent coma.

After many hours of activity, the sleep-wake cycle may be affected by fatigue of the RAS. Sleep centers are then activated, and their neurons release **serotonin**. During *REM sleep*, a stage of sleep characterized by rapid eye movement, neurons in the RAS stimulate heightened activity in certain regions of the brain. After sufficient rest, the inhibitory neurons of the sleep centers become less excitable, and the excitatory neurons of the RAS become more excitable.

(a) Various areas of the cerebral cortex are responsible for specific types of neural processing. (Lateral view of the brain.)

(b) Specific areas of the brain "light up" on positron-emission tomography (PET) scans as an individual performs various tasks. When a specific region of the brain becomes more active, more blood flows to that area. PET scans detect the magnitude of blood flow. Thus, PET scans are pictures of the brain at work, performing specific tasks. The color scale at the right indicates progressively greater activity, from the purple color at the bottom to the white at the top, which indicates maximum activity.

Figure 42-12 Functional areas of the cerebrum

Specific types of activity are associated with certain brain wave patterns

Brain activity can be studied by measuring and recording the electrical potentials, or "brain waves," generated by thousands of active neurons in various parts of the brain. This electrical activity can be recorded by a device known as an *electroencephalograph*. A recording of this electrical activity, called an *electroencephalogram (EEG)*, can be obtained by taping a set of electrodes to standard regions of the scalp and measuring the activity of the cerebral cortex (FIG. 42-14). The EEG shows that the brain is continuously active.

Certain patterns of brain waves are elicited by specific types of activity. For example, when you are resting quietly with eyes closed, your brain emits *alpha rhythm patterns*. In contrast, as you are reading this biology text, your brain is emitting *beta rhythm patterns*, which have a fast-frequency rhythm. Beta rhythm patterns are characteristic of heightened mental activity, such as information processing. During certain stages of sleep, the brain emits slow, high-amplitude *theta waves* and *delta waves*.

Certain brain conditions and diseases change the pattern of brain waves. Individuals with epilepsy, for example, exhibit a recognizable, abnormal wave pattern. The location of a brain tumor or the site of brain damage caused by a blow to the head can sometimes be determined by noting the part of the brain that emits abnormal waves.

Sleep progresses through several stages Sleep is an alteration of consciousness during which there is decreased electrical activity in the cerebral cortex and from which a

(a) Sensory homunculus. This cross section through the anterior region of the parietal lobe shows the distribution of sensory input to the somatosensory area from various parts of the body. The homunculus is proportioned to reflect the relative amount of cerebral cortex that receives sensory information from each body part.

(b) Motor homunculus. This cross section through the posterior part of the frontal lobe shows which area of the cerebral cortex controls each body part. Note that more of the cerebral cortex is devoted to controlling those body structures capable of skilled, complex movement. The primary motor area is involved in coordinated movement of many muscle groups.

Figure 42-13 Maps of the primary sensory and motor areas

person can be aroused. Based on changes in electrical activity, we can identify four stages of *non-REM* sleep during the first hour of sleep. (Note that *REM* is an acronym for *rapid eye movement*.) The deepest sleep is thought to occur during the fourth stage, when it is difficult to awaken the sleeping person. Slow-frequency, higher-amplitude waves (theta and

delta waves) are characteristic of non-REM sleep. This electrical activity is thought to be generated spontaneously by the cerebral cortex when it is not driven by impulses from other parts of the brain. During non-REM sleep, body movement, heart rate, breathing, blood pressure, metabolic rate, and body temperature all decrease.

(a) EEG recordings show brain wave rhythms during different stages of sleep. During non-REM, stage IV sleep, the brain emits slow-frequency, high-amplitude waves. During REM sleep, the brain emits high-frequency activity similar to that of a person who is awake.

Figure 42-14 Brain wave activity and cyclical pattern of sleep

Every 90 minutes or so, a sleeping person enters the REM sleep stage for a time. During this stage (about 20% of total sleep time), the eyes move about rapidly beneath the closed but fluttering lids. Brain waves change to a desynchronized pattern. Everyone dreams, especially during REM sleep. PET scans of sleeping subjects indicate that during REM sleep, blood flow in the frontal lobes is reduced. In contrast, blood flow increases in limbic system areas that produce visual scenes and emotion. Body movement, heart rate, breathing, blood pressure, metabolic rate, and body temperature all increase. Increased secretion of the neurotransmitter GABA by certain neurons in the brain and spinal cord inhibits muscle contraction in some large groups of muscles. This action results in a type of temporary paralysis during REM sleep.

Sleep may have several functions Although most animals have a sleep–wake cycle, neurobiologists are not certain why sleep is necessary. One hypothesis holds that sleep allows certain synaptic connections set during the day to reset. Neurons may strengthen their synaptic contacts with certain neurons and weaken their connections with other neurons. In this way, the brain prunes unneeded synaptic contacts. Memories may be consolidated during REM sleep.

(b) A typical sleep pattern in a young adult.

Another hypothesis suggests that non-REM sleep may provide time for the brain to restore itself. When a person stays awake for unusually long periods, fatigue and irritability result, and even routine tasks are not performed well. For example, fatigue is a leading cause of automobile accidents. Sleep also provides the body with the opportunity to conserve energy and replace glycogen stores.

The limbic system affects emotional aspects of behavior

The **limbic system**, present in all mammals, influences the emotional aspects of behavior, evaluates rewards, and is important in motivation. The limbic system influences the endocrine system and the autonomic division of the nervous system. It plays a role in sexual behavior, biological rhythms, and autonomic responses. The limbic system includes regions of the cerebrum (parts of the prefrontal cortex, cingulate cortex, temporal lobe, basal ganglia, hippocampus, amygdala, and olfactory bulb), regions of the thalamus, the hypothalamus, several nuclei in the midbrain, and neural pathways that connect these structures (FIG. 42-15).

Emotions are feeling states that we experience both physiologically and cognitively. Humans are born with the capacity to experience and express emotions, including fear, anger, sadness, and happiness. The **amygdala** filters incoming sensory information and interprets it in the context of emotional needs and survival. This part of the limbic system is important in the experience of fear and aggression. When it perceives danger, the amygdala sends information to the hypothalamus and to other parts of the brain. The hypothalamus sends signals to the adrenal glands, which release epinephrine (adrenaline) and norepinephrine (noradrenaline). These fight-or-flight hormones activate the body so that we can respond quickly. A traumatic experience can cause the body to remain hyper-alert (see *Inquiring About: The Neurobiology of Traumatic Experience*).

Structures of the limbic system are essential in an infant's bonding with a consistent, nurturing caregiver during the

Figure 42-15 The limbic system

The limbic system consists of a ring of forebrain structures that surround the brain stem and are interconnected by complex neural pathways. This system includes the amygdala, hippocampus, parts of the prefrontal cortex, the cingulate cortex, and areas in the thalamus and hypothalamus. The limbic system is important in assessing danger, in emotional expression, sexual behavior, motivation, and learning.

first year of life. The caregiver encourages the baby to express emotions and helps her learn how to regulate them. The quality of early attachment between child and caregiver affects brain development and future behavior. The development of a secure attachment bond between infant and caregiver is the foundation for all future emotional and social connections between the child and other human beings. Attachment also determines how vulnerable (or resilient) the individual will be to traumatic experiences later in life.

Researchers discovered in the 1950s that the limbic system is part of an important motivational system when they implanted electrodes in certain areas of the brains of laboratory animals. They found that a rat quickly learns to press a lever that stimulates *reward centers* in the brain. In fact, the rat will press the lever as many as 5000 times per hour, choosing this self-stimulation over food and water, until it drops from exhaustion.

The brain has reward centers that give us pleasure when we carry out vital activities such as eating, drinking, and sexual activity. These centers are important in experiencing emotion and in motivation. When stimulated, they activate reward circuits that allow us to feel pleasure in response to certain experiences.

The *mesolimbic dopamine pathway*, a major reward circuit, includes two important midbrain areas: the *substantia nigra* and the adjacent *ventral tegmental area*. These areas, which extend into behavioral control centers in the limbic system, contain the largest group of neurons in the brain that release dopamine.

Novel stimuli associated with reward or pleasure activate these dopamine neurons. The neurons signal information about surprising events or stimuli that predict rewards. Such signals may motivate us to act when something important is happening. Dopamine pathways are also important in the neurobiology of drug addiction (discussed later in this chapter).

As researchers continue to unravel the mechanisms of dopamine pathways, we may better understand such disorders as attention deficit hyperactivity disorder (ADHD) and schizophrenia, conditions associated with excessive amounts of dopamine and other neurotransmitters in the brain. People with these disorders have difficulty filtering out sensory stimuli. The presence of excess dopamine may drive them to attend to so many sensory stimuli that they have difficulty focusing on the most important stimuli.

Learning and memory involve long-term changes at synapses

Neurobiologists are beginning to understand how the nervous system functions, including how we learn and remember. **Learning** is the process by which we acquire knowledge or

skills as a result of experience. For learning to occur, we must be able to remember what we experience. **Memory** is the process of encoding, storing, and retrieving information or learned skills.

To what extent are the brain's functions **hard-wired**, that is, preset? Many areas of the brain once thought to be hard-wired are now known to be flexible and capable of change. Even animals with very simple nervous systems can learn to repeat behaviors associated with reward and to avoid behaviors that cause pain. Such changes in behavior are possible because of **synaptic plasticity**, the ability of synaptic connections to change in response to experience. Such change involves structure and function.

Familiar examples of plasticity in human motor skills include learning to walk, ride a bicycle, or catch a baseball. At first, you were probably clumsy, but with practice your performance became smoother and more precise. For that to happen, changes must occur at synapses in neural circuits. Similarly, the ability to learn languages, solve problems, and perform scientific experiments depends on synaptic plasticity.

What are the mechanisms by which we learn diverse activities, such as skilled movement and the study of biology? Canadian psychologist Donald O. Hebb proposed in 1949 that when two neurons connected by a synapse (i.e., presynaptic and postsynaptic neurons) are active simultaneously, the synapse is strengthened. We can credit Hebb for the axiom "Neurons that fire together, wire together." Hebb's hypotheses have been supported by experimental studies. Experience and practice do affect how neural circuits in our brains organize themselves.

The Neurobiology of Traumatic Experience

Have you ever been involved in a serious automobile accident, or have you been the victim of a violent crime? Are you a combat veteran of Iraq or Afghanistan? Perhaps you are a survivor of a natural disaster, such as a hurricane or earthquake. Or you may have endured childhood neglect or abuse. If you are a survivor of any of these experiences or of some other terrifying event, you may have experienced the effects of trauma. A *traumatic experience* is an event that causes intense fear.

Most of us have strategies for effectively processing *moderately* disturbing experiences. For example, if you were involved in a car accident or were one of the millions of people who watched on television as wounded people were carried away from the scene of a mass shooting, you may have been disturbed by the events you experienced or witnessed. You probably processed what you saw and heard by thinking about it and talking to your friends and family about what happened. You may have dreamed about your experience. As the brain actively reviews and sorts out a disturbing experience, we try to make sense of what happened and we process the memory. The emotional intensity decreases, and we store the memory along with other memories of more ordinary past events. The memory of the uncomfortable experience fades in importance and intensity.

Traumatic events are more difficult to process than moderately disturbing events. If you survived an experience in which you thought you were going to die or be seriously hurt or if you witnessed someone else being wounded or killed, your body's response to real or perceived danger may be very intense. Years later, your body may still be secreting abnormally high amounts of stress hormones and you may remain hyper-alert, your body poised to deal with any new threat.

How does the brain respond in a traumatic experience, and how does the experience affect the brain? When danger threatens, the amygdala sends messages to both the hypothalamus (which signals the autonomic division of the nervous system and the endocrine system) and the cerebral cortex (which allows us to be aware of our experience). The amygdala is programmed to remember the smells, sounds, visual aspects, and sensations that are part of the experience. Until the memories of the experience are fully processed, similar smells, sounds, sights, and sensations remind us of the traumatic event and trigger

the body to prepare for danger. The traumatized individual typically experiences fear and anxiety.

Because they are so overwhelming, traumatic memories are very difficult to process. They cause us so much discomfort and anxiety that we tend to avoid them rather than intentionally focus on them and sort them out. As a result, traumatic memories stay “stuck” in the limbic system. When triggered, the experience may be replayed with its original emotional intensity (a flashback). Some trauma survivors develop post-traumatic stress disorder (PTSD), a condition in which they experience (1) intrusive thoughts, images, sensory experiences, memories, and dreams; (2) an urge to avoid reminders of the traumatic event; and (3) physiological hyperarousal, a condition in which the body remains on high-alert status, scanning the environment for potential danger.

Several studies have shown an association between prolonged trauma (e.g., severe childhood neglect or abuse) and long-term changes in the brain. These changes include EEG abnormalities; smaller size of certain regions of the brain; compromised right brain development (the right brain is specialized for processing information related to emotion, social interaction, and physiological states); differences in neural circuits connecting cortical and subcortical areas (which can decrease the individual's sense of self and lead to poor connections with other people); abnormal concentrations of certain neurotransmitters, which affect mood and the ability to inhibit inappropriate behavior; inappropriate modulation of the limbic system, in which its responses are exaggerated; and long-term changes in the sympathetic nervous system and endocrine response to stress, including a faster, more intense response to stress.

Neuroimaging studies have demonstrated changes in brain function, including over-response by the amygdala and decreased response by the medial prefrontal cortex (which normally inhibits the amygdala). When the amygdala over responds, the individual experiences anxiety, distress, and physiological hyperarousal. These physiological states can lead to intense emotional responses that are rooted in the traumatic experience.

Broca's area, a region in the posterior part of the left frontal cortex, is also affected by trauma. Broca's area is critically important in generating words and thus in expressing language (see Fig. 42-12). Researchers have shown that when subjects are exposed to accounts of their traumatic experiences, activity in Broca's

area decreases. This deactivation appears to be the physiological basis for the difficulty that trauma survivors have describing their experience in words. Trauma survivors have described a state of “speechless terror” that they experience during flashbacks of traumatic experiences. Without words, it is difficult to process and resolve a traumatic experience.

Based on many studies, it is clear that traumatic experiences can cause both structural and functional changes in the brain. The exaggerated responses of the amygdala to harmless stimuli perceived as threatening are disconnected from the influence of the prefrontal cortex that would normally modulate the limbic system. Responses generated by the limbic system are rooted in emotion rather than in rationality and judgment (see figure). PTSD can severely affect and limit one's life. Fortunately, this disorder can be resolved with appropriate treatment.

Learning involves the storage of information and its retrieval

Implicit memory, also called *procedural memory*, is unconscious memory for perceptual and motor skills, such as running, playing a guitar, or texting a message. Implicit memory is about “how” to do something and involves repeating the behavior until it becomes routine. **Declarative memory**, also called *explicit memory*, involves factual knowledge of people,

places, or objects and requires conscious recall of the information. The **hippocampus**, part of the limbic system, is critical in forming and retrieving declarative memories.

How long do you remember? You are constantly bombarded with thousands of bits of sensory information. At this very moment, your eyes are receiving information about the words on this page, the objects around you, and the intensity of the

light in the room. At the same time, you may be hearing a variety of sounds, such as music, your friends talking in the next room, or the hum of an air conditioner. Your olfactory epithelium may sense cologne or the smell of coffee. Maybe you are eating as you read. Sensory receptors in your hands may be receiving information regarding the weight and position of your book or notebook computer. We may hold such sensory information in *immediate memory* for fractions of a second. Most sensory stimuli are not important to remember any longer and are filtered out.

Short-term memory lasts only for seconds or for a few minutes. Typically, we can hold only about seven chunks of information (e.g., seven words or numbers) at a time in short-term memory. Short-term memory lets us recall information for a few minutes. When we look up a phone number, for example, we usually remember it only long enough to call it. If we need the same number an hour later, most of us have to look it up again.

When we select information for **long-term memory**, we must process it. The brain rehearses the material and *encodes* it. We recognize patterns and meaningfully *associate* the stimuli to past experience or knowledge. We practice recalling the information. The hippocampus temporarily holds new information and may integrate various aspects of an experience, including odors, sounds, and other information. The hippocampus helps place our experiences in categories so that they can be stored along with similar memories. We integrate new information with other knowledge already stored in the brain.

Memory consolidation allows memories to be transferred to the cerebral cortex and *stored* for long periods. Consolidation involves expression of genes and protein synthesis, and it depends on new neural connections at synapses. Time (several minutes, hours, or even longer) is required for the brain to *consolidate* a new memory.

If a person suffers a brain concussion, memory of what happened immediately before the incident may be completely lost. This condition is known as *retrograde amnesia*. When the hippocampus is damaged, long-term memory may not be impaired, and the patient may be able to recall information stored in the past. However, new experiences (and the short-term memories of them) can no longer be converted to long-term memories.

Where are memories stored? When large areas of the mammalian cerebral cortex are destroyed, information is lost somewhat in proportion to the extent of lost tissue. No specific area can be labeled the “memory bank.” Rather, memories seem to be stored within many areas of the brain. Visual memories, for example, may be stored in the visual centers of the occipital lobes; similarly, auditory memories may be stored in the temporal lobes. Memories are integrated in many areas of the brain, including association areas of the cerebral cortex, amygdala, hippocampus, thalamus, and hypothalamus. *Wernicke’s area* in the temporal lobe has been identified as an important association area for complex thought processes. Neurons within the association areas form interconnected pathways that permit complicated information transfer.

Retrieval of information stored in long-term memory is of considerable interest, especially to students! The challenge is to find information when you need it. When you seem to forget something, the problem may be that you have not

searched effectively for the memory. Information retrieval can be improved by careful encoding, such as by forming strong associations between items you want to remember. On the other hand, unimportant, unused memories are typically forgotten over time. Forgetting can be useful when it clears the brain of unnecessary information.

Neurobiological changes occur during learning Short-term memory involves changes in the neurotransmitter receptors of postsynaptic neurons. These changes strengthen synaptic connections. The receptors are linked by second messengers (e.g., cyclic AMP) to ion channels in the plasma membrane.

In some types of learning, changes take place in presynaptic terminals or postsynaptic neurons that permanently enhance or inhibit the transmission of impulses. In some cases, specific neurons may become more sensitive than usual to a particular neurotransmitter. Neurons typically transmit action potentials in bursts, and the amount of a neurotransmitter released by each action potential may increase or decrease.

Repeated electrical stimulation of neurons causes a functional change at synapses. When a presynaptic neuron continues to transmit action potentials at a high rate for a minute or longer, there is a long-lasting strengthening of the connection between the presynaptic and postsynaptic neurons. This increased strength of the synaptic connection is known as **long-term potentiation (LTP)**. (*Potentiation* is the process of “strengthening or making more potent.”)

In contrast, low-frequency stimulation of neurons results in a long-lasting *decrease* in the strength of their synaptic connections. This decrease is called **long-term depression (LTD)** (not related to the mood disorder). Information storage and forgetting depend on the strengthening and weakening of synaptic connections brought about by LTP and LTD.

Induction of LTP and LTD requires activation of two types of glutamate receptors: *NMDA receptors* and *AMPA receptors*. (Each of these receptors is named for the compound that artificially activates it. NMDA is the acronym for N-methyl-D-aspartate, and AMPA stands for α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate.) NMDA and AMPA receptors are present on the plasma membranes of postsynaptic neurons. They control the passage of calcium ions into neurons. NMDA receptors respond to the neurotransmitter *glutamate* by opening Ca^{2+} channels. However, when the postsynaptic neuron is at its resting potential, NMDA ion channels are blocked by Mg^{2+} .

A model for the mechanism of LTP is illustrated in **FIGURE 42-16**. A presynaptic neuron releases glutamate, which binds with AMPA receptors. The postsynaptic neuron becomes depolarized. If depolarization of the postsynaptic neuron is sufficiently strong, Mg^{2+} move away from the NMDA receptors, unblocking them. Glutamate can then bind with these receptors, opening Ca^{2+} channels and letting Ca^{2+} move into the cell. Calcium ions appear to be an important trigger for LTP.

Calcium ions act as second messengers that initiate long-term changes ultimately responsible for LTP. For example, calcium ions activate a Ca^{2+} -dependent second-messenger pathway that results in the insertion of more AMPA receptors in the

When glutamate binds to NMDA receptors, Ca^{2+} enter the postsynaptic neuron and activate intracellular signaling systems, leading to changes responsible for LTP.

Figure 42-16 A proposed model for the mechanism of long-term potentiation (LTP)

PREDICT Imagine that Ca^{2+} channels did not open (in step 5). How would this affect synaptic connections and LTP?

postsynaptic membrane. This step is important because additional AMPA receptors increase sensitivity to glutamate. More EPSPs (excitatory postsynaptic potentials) are produced, which strengthens the synapse (i.e., helps maintain the LTP). Recall from Chapter 41 that an EPSP is a change in membrane potential that brings the neuron closer to its threshold level.

Calcium ions also activate a pathway that leads to release of a retrograde signal, a signal that moves backward, from the postsynaptic neuron to the presynaptic neuron. The soluble gas *nitric oxide* (NO) has been identified as the retrograde signal. This signal enhances neurotransmitter release by the presynaptic neuron. Note that this positive feedback loop strengthens the connection between the two neurons.

Long-term memory involves gene expression Gene expression and protein synthesis take place during the process of establishing long-term memory. This process involves slower, but longer-lasting, changes in synaptic connections. Long-term memory depends on activated receptors linked to G proteins (see Chapter 6). Cyclic AMP acts as a second messenger.

A high level of cyclic AMP activates a protein kinase that enters the nucleus, leading to gene activation and protein synthesis. In this process, protein kinase phosphorylates a transcription factor known as *cyclic AMP response element binding protein* (CREB), which then turns on the transcription process of certain genes. CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. The molecules and processes involved in learning and memory have been highly conserved during evolution.

Experience affects development and learning Many studies have demonstrated synaptic plasticity in rats, mice, and other laboratory animals exposed to enriched environments. In contrast with rats housed in standard cages and provided with the basic necessities, those exposed to enriched environments are given toys and other stimulating objects as well as the opportunity to socially interact with other rats. Animals reared in an enriched environment exhibit increased synaptic contacts. They process and remember information more quickly than animals lacking such advantages. Mice exposed to enriched

environments develop significantly greater numbers of neurons in the hippocampus and learn mazes faster than control animals.

Early environmental stimulation can also enhance the development of motor areas in the brain. For example, the brains of rats encouraged to exercise become slightly heavier than those of control animals. Characteristic changes occur within the cerebellum, including the development of larger dendrites.

Apparently, during early life certain critical or sensitive periods of nervous system development occur that are influenced by environmental stimuli. For example, when the eyes of young mice first open, neurons in the visual cortex develop large numbers of dendritic spines (structures on which synaptic contact takes place). If the animals are kept in the dark and deprived of visual stimuli, fewer dendritic spines form. If the mice are exposed to light later in life, some new dendritic spines form, but never as many as develop in a mouse reared in a normal environment.

Studies linking the development of the human brain with environmental experience have demonstrated that early stimulation is important for the sensory, motor, intellectual, and social development of children. Such studies argue for the importance of informed parenting as well as for early childhood education programs, such as Head Start. Investigators have also shown that environmental stimulation is needed to maintain the status of the cerebral cortex in later life.

Language involves comprehension and expression

Language is a form of communication in which we use words to symbolize objects and convey ideas. In about 97% of humans, including most individuals who are left-handed, the areas of the brain responsible for language are located in the left hemisphere (see Fig. 42-12). **Wernicke's area**, located in the temporal lobe, is an important center for language comprehension. This area helps us recognize and interpret both spoken and written words. Wernicke's area also helps us formulate the choice and sequence of words and transfers information to **Broca's area**. Located near motor areas in the left frontal lobe, Broca's area controls our ability to speak. This area is also important in language processing and speech comprehension.

CHECKPOINT 42.4

- How is the human CNS protected? What is the function of the cerebrospinal fluid?
- What are two main functions of the vertebrate spinal cord?
- **VISUALIZE** Draw a lateral view of the human brain and label the major structures, including the lobes; write the functions of each lobe.
- **CONNECT** What role does the limbic system play in emotions? in traumatic experience?
- **CONNECT** In what ways does your success on a biology exam depend on synaptic plasticity? (Include the roles of LTP, gene expression, and NMDA receptors in your answer.)

42.5 The Peripheral Nervous System

LEARNING OBJECTIVES

- 10** Describe the organization of the peripheral nervous system and compare its somatic and autonomic divisions.
- 11** Contrast the sympathetic and parasympathetic divisions of the autonomic system and give examples of the effects of these systems on specific organs.

The peripheral nervous system consists of the sensory receptors, the nerves that link these receptors with the central nervous system, and the nerves that link the CNS with effectors (muscles and glands). The somatic division of the PNS helps the body respond to changes in the external environment. The nerves and receptors that maintain homeostasis despite internal changes make up the autonomic division.

The somatic division helps the body adjust to the external environment

The **somatic division** of the PNS includes the receptors that react to changes in the external environment, the sensory neurons that inform the CNS of those changes, and the motor neurons that adjust the positions of the skeletal muscles that help maintain the body's posture and balance. In mammals 12 pairs of **cranial nerves** emerge from the brain. They transmit information to the brain from the sensory receptors for smell, sight, hearing, and taste. For example, cranial nerve II, the optic nerve, transmits signals from the retina of the eye to the brain. The cranial nerves transmit information to the brain from general sensory receptors, especially in the head region.

Cranial nerves also transmit orders from the CNS to the voluntary muscles that control movements of the eyes, face, mouth, tongue, pharynx, and larynx. Cranial nerve VII, the facial nerve, transmits signals to the muscles used in facial expression and to the salivary glands.

In humans 31 pairs of **spinal nerves** emerge from the spinal cord. Named for the general region of the vertebral column from which they originate, they include 8 pairs of cervical, 12 pairs of thoracic, 5 pairs of lumbar, 5 pairs of sacral, and 1 pair of coccygeal spinal nerves. The ventral branches of several spinal nerves form tangled networks called *plexi* (sing., *plexus*). Within a plexus, the fibers of a spinal nerve may separate and then regroup with fibers that originated in other spinal nerves. Thus, nerves emerging from a plexus consist of neurons from several different spinal nerves.

The autonomic division regulates the internal environment

The **autonomic division** of the PNS helps maintain homeostasis in the internal environment. For example, it regulates the heart rate and helps maintain a constant body temperature. The autonomic system works automatically and without

voluntary input. Its effectors are smooth muscle, cardiac muscle, and glands. Like the somatic system, it is functionally organized into reflex pathways. Receptors within the viscera relay information via afferent nerves to the CNS. The information is integrated at various levels. Then the “decisions” are transmitted along efferent nerves to the appropriate muscles or glands.

Afferent and efferent neurons of the autonomic division lie within cranial and spinal nerves. For example, afferent fibers of cranial nerve X, the *vagus nerve*, transmit signals from many organs of the chest and upper abdomen to the CNS. Its efferent fibers transmit signals from the brain to the heart, stomach, small intestine, and several other organs.

The efferent portion of the autonomic division is subdivided into **sympathetic** and **parasympathetic systems** (TABLE 42-3). Many organs are innervated by both types of nerves. In general, sympathetic and parasympathetic systems have *opposite* effects (FIGS. 42-17 and 42-18). For example, the heart rate is speeded up by messages from sympathetic nerve fibers and slowed by impulses from its parasympathetic nerve fibers. In many cases, sympathetic nerves operate to stimulate organs and to mobilize energy, especially in response to stress, whereas the parasympathetic nerves influence organs to conserve and restore energy, particularly during quiet, calm activities.

Instead of using a single efferent neuron, as in the somatic division, the autonomic division uses a relay of two neurons between the CNS and the effector. The first neuron, called the *preganglionic neuron*, has a cell body and dendrites within the CNS. Its axon, part of a peripheral nerve, ends by synapsing with a *postganglionic neuron*. The dendrites and cell body of the postganglionic neuron are in a ganglion outside the CNS. Its axon terminates near or on the effector.

The sympathetic ganglia are paired, and a chain of them—the *paravertebral sympathetic ganglion chain*—runs on each side of the spinal cord from the neck to the abdomen. Some sympathetic preganglionic neurons do not end in these ganglia but pass on to *collateral ganglia* in the abdomen, close to the aorta and its major branches. Parasympathetic preganglionic neurons synapse with postganglionic neurons in *terminal ganglia* near or within the walls of the organs they innervate.

The sympathetic and parasympathetic systems also differ in the neurotransmitters they release at the synapse with the effector. Both preganglionic and postganglionic parasympathetic neurons secrete acetylcholine. Preganglionic sympathetic

Figure 42-17 Dual innervation of the heart and stomach

Most organs are innervated by both sympathetic and parasympathetic nerves. A sympathetic nerve increases the heart rate, whereas a parasympathetic nerve, the vagus nerve, slows the heartbeat. In contrast, sympathetic nerves slow contractions of the stomach and intestine, whereas the vagus nerve stimulates contractions of these digestive organs. Sympathetic nerves are shown in red; postganglionic fibers are shown as dotted lines.

neurons also secrete acetylcholine, whereas sympathetic postganglionic neurons release norepinephrine.

The autonomic division got its name from the original idea that it was independent of the CNS, that is, autonomous. Neurobiologists have disproved this concept and shown that the hypothalamus and many other parts of the CNS help regulate the autonomic division. Although the autonomic system usually functions automatically, its activities can be consciously influenced.

Biofeedback provides a person with visual or auditory evidence concerning the status of an autonomic body function. For example, a tone may be sounded when blood pressure reaches a desirable level. Using such techniques, individuals have learned to control autonomic activities such as blood pressure, brain wave pattern, heart rate, and blood glucose level. Even certain abnormal heart rhythms can be consciously modified.

Table 42-3 Comparison of Sympathetic and Parasympathetic Systems

	Sympathetic System	Parasympathetic System
General effect	Prepares body to cope with stressful situations	Restores body to resting state after stressful situation; actively maintains normal body functions
Extent of effect	Widespread throughout body	Localized
Duration of effect	Lasting	Brief
Outflow from CNS	Thoracic and lumbar nerves from spinal cord	Cranial nerves and sacral nerves from spinal cord
Location of ganglia	Chain and collateral ganglia	Terminal ganglia
Neurotransmitters released	Preganglionic: acetylcholine Postganglionic: norepinephrine (usually)	Preganglionic: acetylcholine Postganglionic: acetylcholine

Figure 42-18 The sympathetic and parasympathetic systems

Complex as it appears, this diagram has been greatly simplified. *Red lines* represent sympathetic nerves; *black lines* represent parasympathetic nerves. *Dotted lines* represent postganglionic nerves.

CHECKPOINT 42.5

- Compare the function of the somatic division of the PNS with that of the autonomic division of the PNS.
- Contrast the sympathetic and parasympathetic systems with respect to their general effect and the types of neurotransmitters they release.

42.6 Effects of Drugs on the Nervous System

LEARNING OBJECTIVE

- 12** Distinguish among psychological dependence, tolerance, and drug addiction, and describe the biological actions and effects on mood of alcohol, antidepressants, barbiturates, anti-anxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

About 25% of all prescribed drugs are taken to alter psychological conditions, and almost all the commonly abused drugs affect mood. Many act by changing the levels of neurotransmitters within the brain. Changing levels of norepinephrine, serotonin, and dopamine influence mood. Abuse of prescription drugs, particularly painkillers, has become a serious problem, especially among teens and young adults.

According to a national survey on illicit drug use, in 2015 48.8% of persons 12 years and older have used illicit drugs in their lifetimes. During the past month, 17.8% of individuals ages 12 years and older have used illicit drugs.²

Although legal, alcohol is the most commonly used and abused drug. (See *Inquiring About: Alcohol: The Most Abused Drug*.) An estimated 28 million children live with a parent dependent on alcohol and/or illicit drugs.³

TABLE 42-4 lists several commonly used and abused drugs and gives their effects.

Drug addiction is a serious issue

Habitual use of almost any mood-altering drug can result in *psychological dependence*, in which the user becomes emotionally dependent on the drug. When deprived of it, the user craves the feeling of euphoria (well-being) the drug induces. Some drugs induce *tolerance* after several days or weeks; response to the drug decreases, and greater amounts are required to obtain the desired effect. Tolerance often occurs because the liver cells are stimulated to produce more of the enzymes that metabolize and inactivate the drug. It can also occur when the number of postsynaptic receptors that bind with the drug decrease (*down-regulation*).

Drug addiction is a serious societal problem that involves compulsive use of a drug despite negative health consequences and negative effects on the ability to function socially, occupationally, and in school. Use of some drugs, such as tobacco, alcohol, barbiturates, and heroin and other opiates (morphine, codeine, and oxycodone), can also result in physical dependence; physiological changes occur that make the user dependent on the drug. For example, when heroin or alcohol is withheld, the addict suffers characteristic withdrawal symptoms. Physical addiction can occur

² See www.drugabuse.gov/national-survey-drug-use-health.

³ See www.alcoholism-statistics.com/family-statistics/.

when a drug—for example, morphine—has components similar to substances that body cells normally manufacture on their own. Some highly addictive drugs, such as crack cocaine and methamphetamine, do not cause serious withdrawal symptoms.

The neurobiological mechanisms for drug addiction involve the *mesolimbic dopamine pathway*, a major reward circuit (described earlier in this chapter in connection with the limbic system). Many of the neurons in this pathway project from the *ventral tegmental area* in the midbrain and signal neurons in the limbic system, including the amygdala and an area called the *nucleus accumbens*. Projections of this nucleus are thought to be involved in the reinforcement people experience from taking drugs.

Effects on neurons in the mesolimbic dopamine pathway have been demonstrated in nicotine, heroin, amphetamine, and cocaine addiction. For example, amphetamines stimulate dopamine release. Cocaine blocks the reuptake of dopamine into presynaptic neurons, thus prolonging the stimulation (**FIG. 42-19**). Both amphetamines and cocaine can increase dopamine concentration in the limbic system by up to 1000 times normal amounts! Prolonged drug use alters gene expression and changes neuron structure.

Opioid overdose is an epidemic

More than 50,000 people died in 2016 as a result of drug overdoses, mainly from prescription opioids and heroin. According to the Centers for Disease Control and Prevention (CDC), “the United States is in the midst of an opioid overdose epidemic.” Opioids include the illegal drug heroin, synthetic opioids

Figure 42-19 Mechanism of cocaine action

Alcohol: The Most Abused Drug

How does alcohol affect health, families, and society? Alcohol is the fourth leading preventable risk factor for premature death in the United States. In addition, alcohol use is the biggest risk factor for deaths among young people aged 15–29. According to the World Health Organization, alcohol abuse results in 3.3 million deaths worldwide every year.*

Most alcohol-related deaths result from injuries, cancer, liver cirrhosis, and cardiovascular diseases. In addition, alcohol-related violence is a major factor in domestic abuse, road rage, and gang activity.

According to the National Institute of Alcohol Abuse and Alcoholism, “an estimated 679,000 adolescents ages 12–17 had an AUD” (alcohol use disorder) in 2014 (the last year for which statistics are available at the time of this writing). In 2014, approximately 59.8% of college students ages 18–22 years old drank alcohol during the month preceding a survey (compared with 51.5% of others of similar age). Approximately two-thirds of these students also *binge drink*. They acknowledge drinking 5 or more alcoholic beverages at a time. About 12% of college students are *heavy drinkers*. They acknowledge drinking 5 or more alcoholic beverages at least 5 times during the past month. Excessive alcohol intake increases the risk for breast cancer and other cancers, heart disease, sexually transmitted diseases, and unintended pregnancy.†

Almost 3 million students between the ages of 18 and 24 report that they drove a motor vehicle under the influence of alcohol during the past year. According to Mothers against Drunk Driving, teens who drink alcohol kill about 6000 people every year. (The number of deaths is greater than those caused by teen use of all illegal drugs combined.) Every year, about 700,000 college students between the ages of 18 and 24 are assaulted by another student who has been drinking.‡ Almost 2000 college students between the ages of 18 and 24 die each year from alcohol-related nonintentional injuries.

Based on many studies, CDC reports that youth who drink alcohol are likely to experience

serious problems, including disruption of normal growth and sexual development; abnormal brain development that may have lifelong effects; memory problems; school, social, and legal problems; and higher risk for suicide, homicide, and death from alcohol poisoning. Adults who first used alcohol when they were 14 years old or younger were more than five times as likely to have a problem with alcohol dependence or abuse than adults who had their first drink at age 21 or older. Alcohol abuse and dependence result in physiological, psychological, and social impairment and have serious negative consequences for family, friends, and society.

Each of the following has been linked to alcohol abuse:

- More than 30% of all traffic fatalities. (Drugs other than alcohol—e.g., marijuana and cocaine—are involved in about 18% of motor vehicle deaths.)
- Almost 50% of violent crime.
- More than 60% of child-abuse and spouse-abuse cases.
- More than 50% of college sexual assaults.
- About 25% of suicides.
- The birth of thousands of babies each year with serious birth defects. (Fetal alcohol spectrum disorders are the leading cause of preventable intellectual disability in the United States.)
- Increased risk of mouth, larynx, and throat cancers. Alcohol is also a risk factor for primary liver cancer, breast cancer, and colon cancer. These cancers have been linked to regular alcohol consumption.

A single drink—that is, 12 oz of beer, 5 oz of wine, or 1.5 oz of 72-proof liquor—results in a blood alcohol concentration of approximately 20 mg/dL (milligrams per deciliter). This level represents about 0.5 oz of pure alcohol in the blood. Alcohol accumulates in the blood because absorption occurs more rapidly than oxidation and excretion. Every cell in the body can take in alcohol from the blood.

At first, the drinker may feel stimulated, but alcohol actually depresses the CNS. As blood alcohol concentration rises, information processing, judgment, memory, sensory perception, and motor coordination all become progressively impaired. Depression and drowsiness generally occur. Contrary to popular belief, alcohol decreases sexual performance. Some individuals become loud, angry, or violent.

A blood alcohol concentration of 80 mg/dL (0.08 gm/100 mL) legally defines driving under the influence, or DUI. A 170-lb man typically reaches this level by drinking four drinks in an hour on an empty stomach. The National Transportation Safety Board has recommended that states lower the legal allowable blood alcohol concentration to 50 mg/dL (0.05 gm/100 mL). Alcohol metabolism occurs at a fixed rate in the liver. About one drink per hour is metabolized. Only time, not coffee or other remedies, decreases the effects of alcohol intake. Because alcohol inhibits water reabsorption in the kidneys, more fluid is excreted as urine than is consumed in the alcohol. The result is dehydration that, together with a low blood sugar level, may cause the stupor produced by excessive drinking.

In chronic drinkers cells of the CNS adapt to the presence of the drug, which causes *tolerance* (more and more alcohol is needed to experience the same effect) and physical dependence. Abrupt withdrawal can result in sleep disturbances, severe anxiety, tremors, seizures, hallucinations, and psychosis.

Evidence suggests that many neurotransmitters are involved in alcohol addiction, including glutamate, serotonin, GABA, and opioid peptides. Treatment for alcohol addiction includes various forms of psychotherapy and use of anti-craving drugs (such as naltrexone and acamprosate) and disulfiram, which is an aversion drug. The group support offered by Alcoholics Anonymous (AA) has proved effective for many struggling with alcohol dependence. Participation in AA includes attending frequent meetings, having a sponsor within the program, and working on its 12 steps.

* See www.who.int/mediacentre/factsheets/fs349/en/.

† See www.niaaa.nih.gov/alcohol-health/overview-alcohol-consumption/alcohol-facts-and-statistics.

‡ See pubs.niaaa.nih.gov/publications/CollegeFactSheet/CollegeFactSheet.pdf.

(for example, fentanyl), and other prescription drugs used for pain, such as codeine, morphine, oxycodone (OxyContin), and hydrocodone (Vicodin). Prescription opioids account for nearly 50% of all deaths resulting from opioid overdose. Increasingly, deaths from opioids have involved fentanyl, a fast-acting, extremely powerful synthetic opioid. Overdoses can occur within a few minutes.

The drug naloxone blocks the effects of opioids on the CNS. Naloxone can reverse the effects of fentanyl and other

opioid overdose. Some communities have made this life-saving antidote to opioid overdose available in “rescue kits.” The kits can be distributed to first responders, primary care physicians, treatment programs, support groups, and even to high-risk individuals. Unfortunately, the drug companies that manufacture naloxone products (for example, nasal spray, auto-injector) have increased their prices by several hundred percent, making them unaffordable to most individuals.

The FDA has approved several drugs to treat the symptoms of opioid withdrawal. Methadone, an opioid sometimes prescribed for pain management, was the first drug used to treat opioid use disorders. Because methadone itself is addictive, newer drugs (for example, naltrexone) are being used.

CHECKPOINT 42.6

- How do the following drugs affect the CNS: alcohol, antipsychotic drugs, antidepressants, amphetamines, opiates such as oxycodone, and MDMA ("Ecstasy")?

Table 42-4 Effects of Some Commonly Abused Drugs

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
ANTIDEPRESSANTS			
Selective serotonin reuptake inhibitors (SSRIs) (e.g., Prozac, Zoloft, Lexapro, Pristiq)	Relieve depression; used to treat obsessive-compulsive behavior	Block serotonin reuptake; some also block norepinephrine reuptake	Sometimes cause nausea, headache, insomnia, anxiety
Tricyclic antidepressants (e.g., Elavil, Anafranil)	Elevate mood; relieve depression; used to treat obsessive-compulsive behavior	Most block reuptake of biogenic amines (especially norepinephrine), increasing their concentration in synapses	Sedation, weight gain, sexual dysfunction
MAO (monoamine oxidase) inhibitors (e.g., Parnate, Nardil)	Relieve depression	Block enzymatic breakdown of biogenic amines, increasing their concentration in synapses	Liver toxicity, excessive CNS stimulation; overdose may affect blood pressure, may cause hallucinations
ANTI-ANXIETY MEDICATIONS			
Benzodiazepines (e.g., Xanax, Ativan, Valium)	Sedation; induce sleep	Depress CNS; bind to GABA receptors on postsynaptic neuron; increase effectiveness of GABA in opening chloride channels, causing hyperpolarization; cause relaxation of skeletal muscles	Drowsiness, confusion; psychological dependence, addiction; effects additive with alcohol
Barbiturates ("downers") (e.g., phenobarbital)	Sedation; induce sleep; used as anesthesia; used to treat epilepsy	Depress CNS; bind to GABA receptors on chloride channels; the channels open so that more chloride ions move in, causing hyperpolarization	Drowsiness, confusion; psychological dependence, tolerance, addiction; severe CNS depression, resulting in coma and death (especially lethal in combination with alcohol)
ANTIPSYCHOTIC MEDICATIONS			
Phenothiazines (e.g., Thorazine, Mellaril, Stelazine)	Relieve symptoms of schizophrenia; reduce impulsive and aggressive behavior	Block dopamine receptors	Tardive dyskinesia, a neurological syndrome characterized by repetitive involuntary movements, muscle spasms, and shuffling gait
Atypical antipsychotic medications (e.g., Abilify, Risperdal)	Similar to phenothiazines, but also increase motivation	Block dopamine and certain other neurotransmitter receptors	Fewer side effects than with the phenothiazines
NARCOTIC ANALGESICS (also called opiates) (commonly abused prescription drugs, as well as certain street drugs)			
Opioids (e.g., fentanyl, morphine, codeine, oxycodone [OxyContin], hydrocodone [Vicodin]; heroin)	Euphoria; sedation; pain relief	Depress CNS; block pain; mimic actions of endorphins; bind to opiate receptors; like cocaine, inhibit reuptake of dopamine; constrict pupils	Tolerance, psychological dependence, addiction; depress respiration; impair coordination; cause brain damage; convulsions, death from overdose
COCAINE			
"Coke," "rock," "snow"	Brief, intense high with euphoria, followed by fatigue and depression; paranoia	Stimulates release and inhibits reuptake of dopamine, leading to CNS stimulation followed by depression; autonomic stimulation; dilation of pupils; local anesthesia	Mental impairment, convulsions, hallucinations, unconsciousness; death from overdose
MARIJUANA (cannabis)			
"Pot," "weed"; most commonly used illicit substance; main psychoactive ingredient is THC; THC-based drugs are used to treat pain, nausea, and other medical conditions	Euphoria	Impairs coordination; impairs depth perception and alters sense of timing; impairs ability to focus and to learn; impairs short-term memory (probably by decreasing acetylcholine levels in the hippocampus); inflames eyes; causes peripheral vasodilation	Psychological dependence; in large doses, sensory distortions, hallucinations, evidence of lowered sperm counts and testosterone levels

Continued

Table 42-4 Effects of Some Commonly Abused Drugs (continued)

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
AMPHETAMINES			
"Uppers," "pep pills," "crystal meth"; amphetamines (e.g., Dexedrine, levoamphetamine); methamphetamine is a popular club drug	Euphoria, stimulation, hyperactivity	CNS stimulants; stimulate release and block reuptake of dopamine and norepinephrine; enhance flow of impulses in RAS, leading to increased heart rate and blood pressure; pupil dilation	Tolerance, addiction; hallucinations; increased blood pressure; psychotic episodes; death from overdose
Amphetamine-type prescription stimulants commonly used to treat attention deficit hyperactivity disorder (ADHD) (e.g., methylphenidate [Ritalin, Concerta, Adderall])	CNS stimulation, but has calming effect on many children and adults who have ADHD; increases focus	Not addictive at prescribed doses; like cocaine, amphetamines block dopamine transporter, which increases dopamine concentration in synapses	Tolerance and physical addiction occur when abused; when used in higher doses than prescribed, can cause irregular heartbeat and respiration, hallucinations, delusions, convulsions; causes long-term changes in brain function
MDMA (3,4-methylenedioxy-methamphetamine); "Ecstasy," "Molly" (a popular club drug)	Stimulation, sense of pleasure, self-confidence, feelings of closeness to others; mild hallucinogenic	CNS stimulant; damages serotonin pathways in rat and monkey brains	Hyperthermia (excessive body heat); overdose causes rapid heartbeat, high blood pressure, panic attacks, seizures; long-term neurological changes; cognitive impairment
ROHYPNOL, KETAMINE, and GHB			
"Date rape" drugs; rohypnol is a benzodiazepine not legally available in the U.S.	Sedation, anxiety reduction	Rohypnol and ketamine depress the CNS	Psychological dependence, addiction; withdrawal may cause seizures; may be lethal when mixed with alcohol and/or other depressants
PCP (phencyclidine)			
A hallucinogen; "angel dust," "ozone"; originally used as general anesthetic for surgery, but discontinued because it caused delirium with psychotic features; now illegal	Feelings of strength, power, invulnerability, and a numbing effect on the mind; chronic use can cause depression	Affects several neurotransmitters; can cause psychotic symptoms; increase in blood pressure and heart rate; shallow respiration; flushing, profuse sweating; numbness of extremities; difficulty coordinating muscles; changes in body awareness, similar to those associated with alcohol intoxication	Psychological dependence, craving; in adolescents interferes with hormones related to growth and development; chronic use causes memory loss, difficulties with speech, thinking, and learning; causes hallucinations, delusions; high doses cause drop in blood pressure and heart rate, seizures, coma, and death
LSD (lysergic acid diethylamide)			
A hallucinogen; "acid" (manufactured from lysergic acid, which is found in ergot, a fungus that grows on rye and other grains)	Effects unpredictable; typically extreme changes in mood; over-excitation	Alters levels of neurotransmitters in brain; potent CNS stimulator; dilates pupils, sometimes unequally; increases heart rate; raises blood pressure	Impaired judgment leading to irrational behavior; sensory distortions, hallucinations, panic attacks; psychosis; flashbacks
METHAQUALONE (e.g., Quaalude, Sopor)			
A synthetic barbiturate-type drug; no longer legally available in U.S.	Sedative-hypnotic; reduces anxiety; causes euphoria	Depresses CNS; depresses certain spinal reflexes	Tolerance, addiction; overdose can lead to seizures, coma, or death
CAFFEINE			
	Increases mental alertness; decreases fatigue and drowsiness	CNS stimulant; relaxes smooth muscle; stimulates cardiac and skeletal muscle; increases urine volume	Tolerance, psychological dependence, addiction; large amounts cause anxiety, irritability
NICOTINE			
Typically inhaled in tobacco smoke (which contains more than 19 chemical compounds that cause cancer)	Decreases anxiety; increases alertness; may induce a sense of well-being	Stimulates sympathetic nervous system; increases dopamine in mesolimbic pathway	Tolerance, psychological dependence, addiction; withdrawal can cause anxiety, depression, headaches, difficulty concentrating; nicotine stimulates synthesis of lipid in arterial wall, leading to atherosclerosis
ALCOHOL			
(See <i>Inquiring About: Alcohol: The Most Abused Drug</i>)	Euphoria, relaxation, release of inhibitions	Depresses CNS by affecting GABA receptors; impairs vision, coordination, judgment; lengthens reaction time	Tolerance, psychological dependence, addiction; damage to pancreas and liver (e.g., cirrhosis); brain damage; increased risk of depression

SOURCE: Some updated information adapted from the National Institute of Drug Abuse.

Summary: Focus on Learning Objectives

42.1 Invertebrate Nervous Systems: Trends in Evolution (page 883)

1 Contrast nerve nets and radial nervous systems with bilateral nervous systems.

- **Nerve nets** and *radial nervous systems* are typical of radially symmetrical invertebrates, such as cnidarians. An animal with a radial nervous system can respond effectively to predator or prey approaching from any direction.
- In planarian flatworms the *bilateral nervous system* includes *cerebral ganglia* and, usually, two solid ventral nerve cords connected by transverse nerves. Annelids and arthropods typically have a ventral nerve cord and numerous ganglia. The cerebral ganglia of arthropods have specialized regions. Octopods and other cephalopod mollusks have highly developed nervous systems with neurons concentrated in a central region.
- The bilateral nervous system is adaptive for bilaterally symmetrical animals that typically move in a forward direction. Nerve cells concentrate to form **nerves**, **nerve cords**, **ganglia**, and the **brain**; typically, sense organs are concentrated in the head region.

2 Identify trends in the evolution of invertebrate nervous systems.

- Trends in nervous system evolution include increased number and concentration of nerve cells; specialization of function; increased number of association neurons; more complex synaptic contacts; and **cephalization**, the formation of a head.

42.2 Overview of the Vertebrate Nervous System (page 884)

3 Describe the two main divisions of the vertebrate nervous system and summarize their functions.

- The **central nervous system (CNS)**, which consists of the brain and spinal cord, is specialized to integrate incoming information. The **peripheral nervous system (PNS)**, which consists of sensory receptors and nerves, transmits signals between sensory receptors and the CNS, and between the CNS and effectors.

42.3 Evolution of the Vertebrate Brain (page 885)

4 Trace the development of the principal vertebrate brain regions from the hindbrain, midbrain, and forebrain, and compare the brains of fishes, amphibians, reptiles, birds, and mammals.

- In the vertebrate embryo, the brain and spinal cord arise from the **neural tube**. The anterior end of the tube differentiates into the **hindbrain**, **midbrain**, and **forebrain**.
- The hindbrain subdivides into the metencephalon and myelencephalon. The myelencephalon develops into the **medulla**, which contains vital centers and other reflex centers. The fourth ventricle, the cavity of the medulla, communicates with the central canal of the spinal cord. The metencephalon gives rise to the **cerebellum**, which is responsible for muscle tone, posture, and equilibrium, and to the **pons**, which connects various parts of the brain.
- The midbrain is the largest part of the brain in fishes and amphibians. It is their main association area, linking

sensory input and motor output. In reptiles, birds, and mammals, the midbrain serves as a center for visual and auditory reflexes. The medulla, pons, and midbrain make up the **brain stem**.

- The forebrain differentiates to form the diencephalon and telencephalon. The diencephalon develops into the **thalamus** and **hypothalamus**. The **thalamus** is a relay center for motor and sensory information. The **hypothalamus** controls autonomic functions; links nervous and endocrine systems; controls temperature, appetite, and fluid balance; and is involved in some emotional and sexual responses.
- The telencephalon develops into the cerebrum and **olfactory bulbs**. In most vertebrates the **cerebrum** is divided into right and left cerebral hemispheres. In fishes and amphibians, the cerebrum mainly integrates incoming sensory information. In birds the corpus striatum controls complex behavior patterns, such as flying and singing.
- In mammals the *neocortex* accounts for a large part of the **cerebral cortex**, which consists of **gray matter**. The cerebrum has complex association functions.

42.4 The Human Central Nervous System (page 888)

5 Describe the structure and functions of the human spinal cord.

- The human brain and spinal cord are protected by bone and three layers of connective tissue, the **meninges**: the **dura mater**, **arachnoid**, and **pia mater**. The brain and spinal cord are cushioned by **cerebrospinal fluid (CSF)**.
- The **spinal cord** transmits impulses to and from the brain and controls many **reflex actions**. The spinal cord consists of *ascending tracts*, which transmit information to the brain, and *descending tracts*, which transmit information from the brain. Its gray matter contains nuclei that serve as reflex centers.
- A *withdrawal reflex* involves sensory receptors; sensory neurons, interneurons, and motor neurons; and effectors, such as muscles.

6 Describe the structure and functions of the human cerebrum.

- The human cerebral cortex consists of gray matter, which forms folds or **convolutions**. Deep furrows between the folds are called **fissures**.
 - The cerebrum is functionally divided into *sensory areas* that receive incoming sensory information; *motor areas* that control voluntary movement; and **association areas** that link sensory and motor areas and are responsible for learning, language, thought, and judgment. The cerebrum consists of lobes, including the **frontal lobes**, **parietal lobes**, **temporal lobes**, and **occipital lobes**.
 - The **white matter** of the cerebrum lies beneath the cerebral cortex. The **corpus callosum**, a large band of white matter, connects right and left hemispheres. The *basal ganglia*, a cluster of nuclei within the white matter, are important centers for motor function.
- 7 Summarize the sleep–wake cycle and contrast rapid eye movement (REM) sleep with non-REM sleep.**
- The body's main biological clock—the **suprachiasmatic nucleus**—receives information about light and dark and transmits it to other nuclei that regulate sleep.
 - The **reticular activating system (RAS)** is an arousal system; its neurons filter sensory input, selecting which information is transmitted to the cerebrum.
 - The hypothalamus, thalamus, and brain stem regulate the sleep–wake cycle. *Sleep* is an alteration of consciousness with decreased electrical activity in the cerebral cortex.
 - Electrical activity of the cerebral cortex and metabolic rate slow during *non-REM sleep*; dreaming occurs during *REM sleep*.
- 8 Describe the actions of the limbic system; include the role of the amygdala in emotional expression and in response to danger.**
- The **limbic system** affects the emotional aspects of behavior, motivation, sexual activity, autonomic responses, and biological rhythms. The **amygdala** evaluates incoming information and signals danger; it is important in the experience of fear and aggression.
- 9 Summarize how the brain processes information; include a description of synaptic plasticity and the neurobiological changes that take place during learning.**
- **Synaptic plasticity** is the ability of the nervous system to modify synapses, which allows learning and remembering.
 - **Learning** is the process by which we acquire knowledge or skills as a result of experience. **Memory** is the process by which information is encoded, stored, and retrieved.
 - *Immediate memory* holds sensory information for fractions of a second. **Short-term memory** holds a small amount of information for a few minutes. Information

can be transferred from short-term memory to **long-term memory**. The **hippocampus** is important in categorizing information and consolidating memories.

- Learning and memory involve long-term functional changes at synapses. Known as **long-term potentiation (LTP)**, such changes involve increased sensitivity to an action potential by a postsynaptic neuron. **Long-term depression (LTD)** is a long-lasting decrease in the strength of synaptic connections. Long-term memory storage involves gene expression. The transcription factor *CREB* is an important signaling molecule in the memory pathway.

42.5 The Peripheral Nervous System (page 901)

10 Describe the organization of the peripheral nervous system and compare its somatic and autonomic divisions.

- The PNS consists of sensory receptors and nerves, including the **cranial nerves** and **spinal nerves** and their branches. The **somatic division** of the PNS responds to changes in the external environment. The **autonomic division** of the PNS regulates the internal activities of the body.

11 Contrast the sympathetic and parasympathetic divisions of the autonomic system and give examples of the effects of these systems on specific organs.

- The **sympathetic system** permits the body to respond to stressful situations. The **parasympathetic system** influences organs to conserve and restore energy. Many organs are innervated by sympathetic and parasympathetic nerves, which function in opposite ways. For example, the sympathetic system increases heart rate, whereas the parasympathetic system decreases heart rate.

42.6 Effects of Drugs on the Nervous System (page 903)

12 Distinguish among psychological dependence, tolerance, and drug addiction, and describe the biological actions and effects on mood of alcohol, antidepressants, barbiturates, anti-anxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

- Many drugs alter mood by increasing or decreasing the concentrations of specific neurotransmitters within the brain. See Table 42-4 for a summary of these drugs.
- Habitual use of mood-altering drugs can result in *psychological dependence* or *drug addiction*. Many drugs induce *tolerance*, in which the body's response to the drug decreases so that greater amounts are needed to obtain the desired effect.

Test Your Understanding

Know and Comprehend

1. A radially symmetrical animal such as *Hydra* is likely to have (a) a forebrain (b) a nerve net (c) cerebral ganglia (d) a ventral nerve cord (e) cerebral ganglia and a nerve net
2. Which part of the vertebrate brain maintains posture, muscle tone, and equilibrium? (a) cerebrum (b) medulla (c) cerebellum (d) neocortex (e) thalamus
3. The main association area in the amphibian brain is the (a) cerebrum (b) medulla (c) neocortex (d) midbrain (e) arachnoid
4. The suprachiasmatic nucleus (a) secretes melatonin (b) stimulates long-term potentiation (LTP) in the hippocampus (c) filters incoming sensory information and determines whether it is threatening (d) is critical in memory consolidation (e) is important in regulating the sleep–wake cycle

5. The heart rate is slowed by (a) sympathetic nerves (b) parasympathetic nerves (c) rapid firing in the corpus callosum (d) both sympathetic and parasympathetic nerves (e) the hippocampus working together with sympathetic nerves
6. Amphetamines (a) affect neurons in the mesolimbic dopamine pathway (b) decrease the amount of dopamine secreted (c) affect the CNS in the same way as alcohol (d) are often prescribed to reduce anxiety (e) are CNS depressants

Apply and Analyze

7. Which sequence best describes transmission of information in a withdrawal reflex? 1. afferent neuron transmits signal to CNS 2. muscle contracts 3. reception by sensory neuron 4. interneuron in CNS integrates information 5. efferent neuron transmits signal (a) 3, 1, 4, 5, 2 (b) 2, 1, 4, 5, 3 (c) 3, 5, 1, 4, 2 (d) 3, 1, 5, 4, 2 (e) 5, 3, 1, 4, 2
8. **VISUALIZE** Label the diagram of the human brain.

9. **EVOLUTION LINK** What general trends can you identify in the evolution of the vertebrate brain?

Evaluate and Synthesize

10. **SCIENCE, TECHNOLOGY, AND SOCIETY** Imagine that you have just become a parent. What kinds of things can you do to enhance the development of your child's intellectual abilities?
11. What is the adaptive function of the limbic system when an alligator is chasing you?
12. **EVOLUTION LINK** CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. What does that suggest about the evolution of learning and memory?
13. Hypothesize a possible relationship between inheritance and intelligence based on gene activation during information processing.

43 Sensory Systems

Have you heard dolphins make clicking sounds? Humans can hear only a limited number of the wide range of sound frequencies that dolphins emit. Dolphins, bats, and a few other vertebrates detect distant objects by *echolocation*, sometimes called biosonar. Echolocation works something like radar but uses sound rather than radio waves. For example, a bat emits high-pitched sounds that bounce off objects in its path and echo back. By rapidly responding to the echo, the bat skillfully avoids obstacles and captures prey (see photograph). Using echolocation, bats and dolphins determine the size, shape, texture, and density of an object as well as its location.

The ability to detect sounds emitted by some foraging bats has evolved in certain moths and other insect prey. Through the course of evolution, some species of bats have adapted to this ability of their prey and now emit even higher-frequency sounds that their prey cannot detect.

Sensory systems transfer information from the outside world to the animal. They inform the animal about predators, food, water, possible mates, temperature, and other changes in the environment. The kinds of sensory receptors an animal has and the way in which its brain *perceives* incoming sensory information determine what the animal's world is like. We humans live in a world of rich colors, numerous shapes, and varied sounds. But we cannot hear the high-pitched whistles that are audible to dogs and cats or the ultrasonic echoes by which bats navigate. Unlike some migratory animals, we cannot use magnetic fields to navigate. Nor do we ordinarily recognize our friends by their distinctive odors. And although vision is our dominant and most refined sense, we are blind to the ultraviolet (UV) hues that light up the world for insects.

We humans are most familiar with the senses of sight, hearing, smell, taste, and touch, but we have other senses. In fact, touch is a

KEY CONCEPTS

- 43.1** Sensory processing includes sensory reception, energy transduction, transmission of signals, and interpretation in the central nervous system (CNS).
- 43.2** Thermoreceptors respond to heat and cold.
- 43.3** Some predatory species of sharks, rays, and bony fishes have electroreceptors that detect electric fields generated in the water by the activity of other animals.
- 43.4** Dendrites of certain sensory neurons are nociceptors (pain receptors).
- 43.5** Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement.
- 43.6** Most animals have chemoreceptors for taste and smell that detect chemical substances in food, water, and air.
- 43.7** Almost all animals have photoreceptors that respond to light, and most animals have eyes that form images; the retina of the vertebrate eye contains photoreceptor cells called rods and cones.

PHOTO: Bats are guided by echoes. This Western pipistrelle bat (*Pipistrellus hesperus*) homes in on a moth over desert scrub, near Pine Creek in the John Day Fossil Beds National Monument, Clamo Unit, Oregon. Michael Durham/Minden Pictures/Getty Images

compound sense that allows us to detect pressure, pain, and temperature. Some sensory receptors allow us to sense balance, muscle tension, and joint position, providing us with an awareness of our bodies.

In this chapter we first examine how sensory systems function. Next we introduce the major types of sensory receptors. We then discuss several types of sensory systems with emphasis on auditory and visual systems.

43.1 How Sensory Systems Work

LEARNING OBJECTIVES

- 1 Describe how sensory systems function; include descriptions of sensory receptors, energy transduction, receptor potential, sensory adaptation, and perception.
- 2 Classify sensory receptors according to the location of the stimuli to which they respond and according to the types of energy they transduce.

A **sensory receptor** detects information about changes in the external or internal environment. Sensory receptors consist of the endings of afferent neurons or cells in close contact with neurons that are specialized to detect specific types of energy in the environment. Along with other types of cells, sensory receptors make up complex **sense organs**, such as the eyes, ears, nose, and taste buds. A human taste bud, for example, consists of taste receptor cells that detect chemicals dissolved in saliva, and epithelial cells that support the receptor cells.

Several steps take place in sensory processing, including sensory reception, energy transduction, transmission of the signal, and interpretation in the brain. With minor variations, all sensory systems operate in this way.

Sensory receptors receive information

Sensory receptors receive stimuli from the external or internal environment. In the process of reception, they absorb a small amount of energy from some stimulus. Each kind of sensory receptor is especially sensitive to one particular form of energy. For example, the photoreceptors of the human eye are stimulated by an extremely faint beam of light; similarly, taste receptors are stimulated by a minute amount of a chemical compound.

Sensory receptors transduce energy

Sensory receptors *transduce*, or convert, the energy of the stimulus into electrical signals, the information currency of the nervous system. This process is known as *energy transduction*. When unstimulated, a sensory receptor maintains a *resting potential*, that is, a difference in charge between the inside and outside of the cell (see Chapter 41). Transduction couples a stimulus with the opening or closing of ion channels in the plasma membranes of sensory receptors. The permeability of the plasma membrane to various ions is altered.

A change in ion distribution causes a change in voltage across the membrane. If the difference in charge increases, the receptor becomes hyperpolarized. If the potential decreases, the receptor becomes depolarized. A change in membrane potential is a **receptor potential**. A receptor potential does not directly trigger an action potential. Like an excitatory postsynaptic potential, or EPSP (see Chapter 41), the receptor potential is a **graded potential** in which the magnitude of change depends on the strength of the stimulus.

If the receptor is a separate cell, receptor potentials stimulate the release of a neurotransmitter, which flows across the synapse and binds to receptors on an *afferent neuron*, or **sensory neuron** (FIG. 43-1). When a sensory neuron becomes sufficiently depolarized to reach its threshold level, an action potential is generated. Thus, receptor potentials can generate action potentials that transmit information to the central nervous system (CNS).

Many receptors are specialized neurons rather than separate cells. In these neurons the specialized region of the plasma membrane that transduces energy does not generate action potentials. Current generated by receptor potentials flows to a region along the axon where an action potential can be generated.

We can summarize the process of sensory reception as follows:

stimulus (such as light energy) → sensory receptor absorbs energy from stimulus → energy transduction of stimulus into electrical energy → receptor potential produced → action potential in sensory neuron → signal transmitted to CNS

Sensory input is integrated at many levels

Sensory integration begins in the receptor itself. For example, receptor potentials produced by various stimuli are integrated by summation (see Chapter 41). However, integration occurs mainly in the spinal cord and at various locations in the brain.

Sensory receptors adapt to stimuli Many sensory receptors do not continue to respond at the initial rate, even if the stimulus continues at the same intensity. This change in response rate, called **sensory adaptation**, occurs for two reasons. First, during a sustained stimulus, the receptor sensitivity decreases and produces a smaller receptor potential (resulting in a lower frequency of action potentials in the sensory neurons). Second, changes take place at synapses in the neural pathway activated by the receptor. For example, the release of neurotransmitter from a presynaptic terminal may decrease in response to a series of action potentials.

Some receptors, such as those for pain or cold, adapt so slowly that they continue to trigger action potentials as long as the stimulus persists. Other receptors adapt rapidly, permitting us to ignore persistent unpleasant or unimportant stimuli. For example, when you first pull on a pair of tight jeans, your pressure receptors let you know that you are being squished, and you may feel uncomfortable. Soon, though, these receptors adapt, and you hardly notice the sensation of the tight fit. In the same way, people quickly adapt to odors

Figure 43-1 How sensory systems work

Sensory receptors receive stimuli from the environment. They transduce the energy of the stimulus into electrical signals and thus generate receptor potentials. Action potentials are generated in sensory neurons that transmit signals to the CNS, where they are integrated.

that at first seem to assault their senses. Other examples are light adaptation when you step outside into bright sunlight and dark adaptation when you step into a dimly lit room. Sensory adaptation enables an animal to discriminate between unimportant background stimuli that can be ignored and new or important stimuli that require attention.

Sensation depends on transmission of a coded message How do you know whether you are seeing a blue sky, tasting a doughnut, or hearing a note played on a piano? All action potentials are qualitatively the same. Light of the wavelength 450 nm (blue), sugar molecules (sweet),

and sound waves of 440 hertz (Hz) (A above middle C) all cause transmission of similar action potentials. Our ability to differentiate stimuli depends on both the sensory receptor itself and on the brain. We can distinguish the color of a blue sky from the scent of cologne, a sweet taste from a light breeze, or the sound of a piano from the heat of the sun because cells of each sensory receptor are connected to specific neurons in particular parts of the brain. Because a receptor normally responds to only one type of stimulus (e.g., light), the brain interprets a message arriving from a particular receptor as meaning that a certain type of stimulus occurred (such as a flash of color).

When stimulated, a sensory receptor initiates what might be considered a coded message, composed of action potentials transmitted by sensory neurons. This coded message is later decoded in the brain. Impulses from the sensory receptor may differ in the (1) total number of sensory neurons transmitting the signal, (2) specific neurons transmitting action potentials and their targets, (3) total number of action potentials transmitted by a given neuron, and (4) frequency of the action potentials transmitted by a given fiber. The intensity of a stimulus is coded by the frequency of action potentials fired by sensory neurons during the stimulus. A strong stimulus results in a greater depolarization of the receptor membrane, so the sensory neuron fires action potentials with greater frequency than would a weak stimulus. This variation is possible because, as a graded response, the receptor potential can vary in magnitude.

The difference in sound intensity between the gentle rustling of leaves and a loud clap of thunder depends on the number of neurons transmitting action potentials as well as the frequency of the action potentials transmitted by each neuron. Just how the sensory receptor initiates different codes and how the brain analyzes and interprets them to produce various sensations are not yet completely understood.

Sensation takes place in the brain. Interpretation of the message and the type of sensation depends on which interneurons receive the message. The rods and cones of the eye do not see. When stimulated, they send a message to the brain that interprets the signals and translates them into a rainbow, an elephant, or a child. Artificial (e.g., electrical) stimulation of brain centers can also result in sensation. In contrast, many sensory messages never give rise to sensations at all. For example, certain chemoreceptors sense internal changes in the body but never stir our consciousness.

Sensory perceptions are constructed by the mind

The brain interprets sensations by converting them to perceptions of stimuli. Sensory **perception** is the process of selecting, interpreting, and organizing sensory information.

(a) Your perception of the same visual input can vary. Do you see a wineglass or the profiles of two faces?

(b) Do you “see” a white square? If so, your brain is completing a familiar pattern suggested by the right-angle wedges taken out of each of the four red circles.

Figure 43-2 Visual perception

Sensory perceptions are constructed by the mind by comparing present sensory experience with our memories of past experiences. You may perceive the incoming visual and auditory input of a hissing snake very differently than does your friend who is terrified of snakes or a herpetologist who studies them. Perceptions are influenced by our state of mind at the time we receive sensory information. Optical illusions demonstrate that the brain can interpret sensory stimuli in various ways (**FIG. 43-2a**). The brain also modifies stimuli to make them more complete, familiar, or logical (**FIG. 43-2b**).

We can classify sensory receptors based on location of stimuli or on the type of energy they transduce

Sensory receptors can be classified according to the location of the stimuli to which they respond. **Exteroceptors** receive stimuli from the outside environment, enabling an animal to know and explore the world, search for food, find and attract a mate, recognize friends, and detect enemies. **Interoceptors** are sensory receptors within body organs that detect changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood. You are not usually aware of messages sent to the CNS by these receptors as they work continuously to maintain homeostasis. You become aware of their activity when they signal certain internal conditions such as thirst, hunger, nausea, pain, and orgasm.

We can also classify sensory receptors based on the type of energy they transduce (**TABLE 43-1**). *Thermoreceptors* respond to heat and cold. *Electroreceptors* sense differences in electrical potential. *Electromagnetic receptors* are electroreceptors that are sensitive enough to detect Earth’s magnetic field. *Nociceptors* (pain receptors) respond to mechanical, temperature, and other stimuli that could be damaging. *Mechanoreceptors* transduce mechanical energy—touch, pressure, gravity, stretching, and movement—and these receptors convert mechanical forces directly into electrical signals. *Chemoreceptors* transduce the energy of certain chemical compounds, and *photoreceptors* transduce light energy.

CHECKPOINT 43.1

- **CONNECT** In what way does a receptor potential differ from an action potential?
- **PREDICT** Imagine that you are hiking along a bay and notice a really strong, unpleasant odor. How might sensory adaptation be helpful?
- How is sensory information integrated?
- Identify five kinds of sensory receptors based on the type of energy they transduce. What is the specific function of each?

Table 43-1 Classification of Receptors by Type of Energy They Transduce

Type of Receptor	Type of Energy Transduced	Examples
Thermoreceptors	Heat	Temperature receptors in blood-sucking insects and ticks; pit organs in pit vipers; nerve endings and receptors in skin and tongues of many animals
Electroreceptors and electromagnetic receptors	Electrical; receptors detect differences in electrical potential	Electrical currents in water used to navigate by many fish and some amphibian species; some animals use magnetic fields for orientation and migration
Nociceptors (pain receptors)	Mechanical; physical force such as strong touch, pressure; heat, temperature extremes; damaging chemicals	Neuron endings in skin and other tissues
Mechanoreceptors	Mechanical; change shape as a result of being pushed or pulled	Tactile receptors (free nerve endings, Merkel cells, Meissner corpuscles, Ruffini endings, Pacinian corpuscles); respond to touch and pressure Proprioceptors respond to movement and body position Muscle spindles respond to muscle contraction Golgi tendon organs respond to stretch of a tendon Joint receptors respond to movement in ligaments Statocysts in invertebrates have hair cells that respond to gravity Lateral line organs in fish detect vibrations in the water; respond to waves and currents Vestibular apparatus Hair cells in saccule and utricle respond to gravity, linear acceleration Hair cells in semicircular canals respond to angular acceleration Hair cells in organ of Corti in cochlea; respond to pressure waves (sound)
Chemoreceptors	Specific chemical compounds	Taste buds; olfactory epithelium
Photoreceptors	Light	Eyespots; ommatidia in compound eye of arthropods; rods and cones in retina of vertebrates

43.2 Thermoreceptors

LEARNING OBJECTIVE

3 Identify three functions of thermoreceptors.

Thermoreceptors respond to heat and cold. Mosquitoes, ticks, and other blood-sucking arthropods use *thermoreception* to find endothermic hosts. Some arthropods have thermoreceptors on their antennae that are sensitive to temperature changes of less than 0.5°C.

Pit vipers (which include rattlesnakes) and some pythons and boas use thermoreceptors to locate their prey, and perhaps, to detect predators (**FIG. 43-3**). These thermoreceptors have heat-sensitive ion channels that detect infrared radiation.

In mammals, which are endothermic, free nerve endings (and, perhaps, specialized receptors) in the skin and tongue detect temperature changes in the outside environment. In addition, pain receptors sense extreme temperatures that pose a threat to the body. Thermoreceptors in the hypothalamus detect internal changes in temperature. They also receive and integrate information from receptors on the body surface. The hypothalamus then initiates homeostatic mechanisms that ensure a constant body temperature.

Figure 43-3 Thermoreception

The pit organ of the bamboo viper (*Trimeresurus gramineus*) is a sense organ located between each eye and nostril. Thermoreceptors in the pit organ can detect the heat emitted by an endothermic animal up to a distance of 1 to 2 m.

CHECKPOINT 43.2

- What are the functions of thermoreceptors in mosquitoes, snakes, and mammals?

43.3 Electroreceptors and Magnetic Reception

LEARNING OBJECTIVE

- 4 Describe the functions of electroreceptors and identify the functions of magnetic reception.

Electroreceptors sense differences in electrical potential. Some predatory species of sharks, rays, and bony fishes detect electric fields generated in the water by the muscle activity of their prey. Electroreception also appears important in communication, such as in recognizing a potential mate. Males and females have different frequencies of electric discharge.

Several groups of fishes have electric organs, specialized muscle or nerve cells that emit electrical signals and receive a feedback signal. In species that produce a weak electric current, electroreceptors may help in navigation. This mechanism is particularly useful in murky water, where visibility and olfaction are poor.

A few fishes, such as electric eels or electric rays, have electric organs in their heads capable of delivering powerful shocks (up to several hundred volts) that stun prey or predators. Weaker electrical signals are emitted continuously to help in assessing the environment, orienting themselves, and communicating.

Some bacteria, mollusks, crustaceans, insects, bony fishes, amphibians, reptiles, birds, and a few mammals detect Earth's magnetic fields and use this information to orient themselves. Migratory birds and sea turtles are well-known examples of animals that use magnetic fields to navigate (discussed further in Chapter 52).

Earth's magnetic fields penetrate organisms, so specialized receptors may not be required. However, certain receptors of sharks, rays, and skates appear to sense magnetic fields. For example, when a shark swims across one of Earth's magnetic field lines, *electromagnetic receptors* may detect changes that occur in electric currents. This information, which is integrated in the brain, helps the animal orient itself.

CHECKPOINT 43.3

- What are two functions of electroreceptors?
- How do animals use electromagnetic reception?

43.4 Nociceptors

LEARNING OBJECTIVE

- 5 Describe the functions of nociceptors and identify the roles of substance P and endorphins.

Pain receptors, called **nociceptors** (from the Latin *nocere*, meaning “to injure”), are free nerve endings (dendrites) of certain sensory neurons found in almost every tissue. Three main types of nociceptors have been identified: (1) mechanical nociceptors respond to strong tactile stimuli such as cutting, crushing, or pinching; (2) thermal nociceptors respond to temperature extremes (temperatures above 45°C or below 5°C); and (3) polymodal nociceptors respond to a variety of damaging stimuli, including certain chemicals.

When stimulated, nociceptors transmit signals through sensory neurons to interneurons in the spinal cord. These sensory neurons release the neurotransmitters *substance P* and *glutamate*. **Substance P** activates interneurons that transmit the pain message to the opposite side of the spinal cord. Ascending pathways then transmit the message upward to the brain stem and thalamus, where pain perception begins. From the thalamus, impulses are sent into the somatosensory areas that localize the pain. Signals are transmitted to the prefrontal cortex, allowing us to become fully aware of our pain and to evaluate the situation. Information is also sent from the brain stem and thalamus to the limbic system, which generates an emotional response to the injury. **Glutamate** stimulates interneurons in the spinal cord that transmit pain signals to cortical areas of the brain.

Mammals have an analgesic system that inhibits pain signals in the spinal cord. Certain interneurons release **endorphins** and **enkephalins**, neurotransmitters that bind with opiate receptors on the terminals of sensory neurons in the spinal cord. This binding inhibits release of substance P, which stops transmission of the pain signal.

CHECKPOINT 43.4

- What is the function of each main type of nociceptor?
- What is the function of substance P? of endorphins?

43.5 Mechanoreceptors

LEARNING OBJECTIVES

- 6 Compare the functions and mechanisms of action of the following mechanoreceptors: tactile receptors, proprioceptors, statocysts, hair cells, and lateral line organs.
- 7 Compare the structure and function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.
- 8 Trace the path taken by sound waves through the structures of the ear and explain how the organ of Corti functions as an auditory receptor.

Mechanoreceptors are activated when they change shape as a result of being mechanically pushed or pulled. They transduce mechanical energy, permitting animals to feel, hear, and maintain balance. These receptors provide information about the shape, texture, weight, and spatial relationships of objects in the external environment. Some mechanoreceptors are extremely sensitive. For example, alligators have pressure

receptors on their faces that can detect the movement in the surrounding water caused by a single drop of falling water.

Certain mechanoreceptors enable an animal to maintain its body position with respect to gravity (for us, head up and feet down; for a dog, dorsal side up and ventral side down; for a tree sloth, ventral side up and dorsal side down). When displaced from its normal position, the animal quickly adjusts its body to return to its normal orientation. Mechanoreceptors continuously send information to the CNS regarding the position and movements of the body. These receptors also provide information about the operation of internal organs. For example, they inform us about the presence of food in the stomach, feces in the rectum, urine in the bladder, and a fetus in the uterus.

Tactile receptors are located in the skin

The simplest mechanoreceptors are free nerve endings in the skin. They detect touch, pressure, vibration, and pain when stimulated by objects that contact the body surface. In many invertebrates and vertebrates, *tactile* (touch) *receptors* lie at the base of a hair or bristle. These receptors may sense the body's orientation in space with respect to gravity. They may

also detect air and water vibrations and contact with other objects. A tactile receptor is stimulated indirectly when the hair is bent or displaced. The stimulus mechanically distorts ion channel proteins in the plasma membrane of the receptor, leading to net entry of Na^+ . A receptor potential develops in the afferent neuron, and action potentials may be generated. This type of receptor responds only when the hair is moving. Even though the hair may be maintained in a displaced position, the receptor is not stimulated unless there is motion.

Thousands of specialized tactile receptors are located in mammalian skin (FIG. 43-4). *Merkel cells* form discs in the deep regions of the epidermis that extend down into the dermis. Merkel cells are important in sensing light touch and enable us to distinguish among the softness of a baby's skin, the fuzziness of a peach, or the hardness of a book cover. They adapt slowly, permitting us to know that an object continues to touch the skin.

Three types of mechanoreceptors in the skin—Meissner corpuscles, Ruffini endings, and Pacinian corpuscles—have encapsulated endings. *Meissner corpuscles*, located in the upper dermis, are sensitive to light touch and vibration. They adapt quickly to a sustained stimulus. *Ruffini endings*, located in the dermis, inform us of heavy, continuous pressure and stretch

(a) Mechanoreceptors in human skin. This diagrammatic section through the human skin illustrates several types of mechanoreceptors that respond to touch and pressure. Also shown are free nerve endings that respond to pain.

(b) Pacinian corpuscle, a deep pressure receptor.

(c) Pacinian corpuscles sense mechanical forces. Pressure causes Na^+ channels to open, depolarizing the axon.

Figure 43-4 Sensory receptors in human skin

of the skin. They adapt very slowly and are thought to provide information about the position of our fingers and hand.

Pacinian corpuscles, located deep in the dermis, are sensitive to deep pressure that causes rapid movement of the tissues. They are especially sensitive to stimuli that vibrate. The Pacinian corpuscle consists of a neuron ending surrounded by concentric connective tissue layers interspersed with fluid. Compression causes displacement of the layers, which stimulates the axon. Even though the displacement is maintained under steady compression, the receptor potential rapidly falls to zero, and action potentials cease—an excellent example of sensory adaptation.

Proprioceptors help coordinate muscle movement

Proprioceptors help animals maintain the position of the body and its parts. Located within muscles, tendons, and joints, proprioceptors continuously respond to tension and movement. With their input, an animal can perceive the positions of its arms, legs, head, and other body parts along with the orientation of its body as a whole. This information is essential for all forms of locomotion and for all coordinated and skilled movements, from spinning a cocoon to completing a reverse one-and-a-half dive with a twist. With the help of proprioceptors, we carry out activities such as dressing or playing the piano even in the dark.

Vertebrates have three main types of proprioceptors:

- (1) **muscle spindles**, which detect muscle movement (FIG. 43-5);
- (2) **Golgi tendon organs**, which respond to tension in contracting

muscles and in the tendons that attach muscle to bone; and (3) **joint receptors**, which detect movement in ligaments. Impulses from proprioceptors help coordinate the contractions of the several distinct muscles that may be involved in a single movement. Without such receptors, complicated, skilled acts would be impossible. Proprioceptors are also important in maintaining balance.

Proprioceptors continuously send signals to inform the brain about position. Although we are less aware of them, proprioceptors are probably more numerous and more continually active than any of the other sensory receptors. As long as a stimulus is present, receptor potentials are maintained (although not at constant magnitude) and action potentials continue to be generated. The mammalian muscle spindle, one of the more versatile stretch receptors, helps maintain muscle tone. It is a bundle of specialized muscle fibers, with a central region encircled by sensory neuron endings. These neurons continue to transmit signals for a prolonged period, in proportion to the degree of stretch.

Many invertebrates have gravity receptors called statocysts

Statocysts are the simplest organs of equilibrium. Jellyfish and crayfish are among the many aquatic invertebrates that have these gravity receptors (FIG. 43-6). A statocyst is basically an infolding of the epidermis lined with receptor cells called *sensory hair cells*. These cells are equipped with sensory hairs

Figure 43-5 Proprioceptors

Muscle spindles detect muscle movement. A muscle spindle consists of an elongated bundle of specialized muscle fibers. Golgi tendon organs respond to tension in muscles and their associated tendons.

Figure 43-6 A statocyst

Many invertebrates have statocysts, receptors that sense gravitational force and provide information about orientation of the body with respect to gravity.

(not true hairs). The cavity contains one or more **statoliths**, tiny granules of loose sand grains or calcium carbonate held together by an adhesive material secreted by cells of the statocyst. Normally, the particles are pulled downward by gravity and stimulate the sensory hair cells.

When the animal changes position, the statocyst tilts, and the statolith moves in the same direction. This movement bends the sensory hairs. Each sensory hair cell responds maximally when the animal is at a particular position with respect to gravity. The mechanical displacement results in receptor potentials and action potentials that inform the nervous system of the change in position. By “knowing” which sensory cells are firing, the animal knows where “down” is and can correct any abnormal orientation.

In a classic experiment, the function of the statocyst was demonstrated by replacing the sand grains with iron filings in the statocysts of crayfish. The force of gravity was overcome by holding magnets above the animals. The iron filings were attracted upward toward the magnets, and the crayfish began to swim upside down in response to the new information provided by their gravity receptors.

Hair cells are characterized by stereocilia

Vertebrate **hair cells** are mechanoreceptors that detect movement. They are the sensory receptors in the lateral line of fishes that detect water movement (FIG. 43-7). Hair cells also help maintain position and equilibrium and are important in hearing.

The surface of a vertebrate hair cell typically has a single long **kinocilium** and many shorter **stereocilia**, hairlike projections that increase in length from one side of the hair cell to the other (see Fig. 43-7c). A kinocilium is a true cilium with a 9 + 2 arrangement of microtubules (see Chapter 4). In contrast, stereocilia are not really cilia. They are microvilli that contain actin filaments.

Mechanical stimulation of the stereocilia causes voltage changes. Mechanical stimulation in one direction causes depolarization and release of neurotransmitter, whereas mechanical stimulation in the opposite direction results in hyperpolarization. However, hair cells have no axons and do not produce their own action potentials. Rather, they release neurotransmitter that depolarizes associated neurons.

Lateral line organs supplement vision in fishes

Lateral line organs of fishes and aquatic amphibians detect vibrations in the water. They inform the animal of obstacles in its way and of moving objects such as prey, enemies, and others in its school. Typically, the lateral line organ is a long canal running the length of the body and continuing into the head. The canal is lined with sensory hair cells. The tips of the stereocilia are enclosed by a **cupula**, a mass of gelatinous material secreted by the hair cells.

Pressure waves, currents, and even slight movement in the water cause vibrations in the lateral line organ. As the water moves the cupula, the stereocilia bend. This motion changes the membrane potential of the hair cell, which may then release neurotransmitter. If an associated sensory neuron is sufficiently stimulated, an action potential is dispatched to the CNS.

The vestibular apparatus maintains equilibrium

When you think of the ear, you probably think of hearing. However, in vertebrates the main function of the ear is to help maintain equilibrium. Many vertebrates do not have outer or middle ears, but all have inner ears (FIG. 43-8). In mammals the *inner ear* includes organs of equilibrium equipped with hair cells that sense the position of the body with respect to gravity.

Figure 43-7 Lateral line organs of fishes

These mechanoreceptors detect vibrations in the water, informing the fish of obstacles or moving objects.

(a) Structure of the human ear, anterior view.

(b) The vestibular apparatus. The saccule, utricle, and semicircular canals together make up the vestibular apparatus. The utricle and saccule are best seen in the posterior view shown here.

Figure 43-8 The human ear: hearing and equilibrium

The inner ear is a group of interconnected canals and sacs, called the **labyrinth**, which includes a membranous labyrinth that fits inside a bony labyrinth. In mammals the membranous labyrinth has two saclike chambers—the **saccule** and the **utricle**—and three **semicircular canals**. Collectively, the saccule, utricle, and semicircular canals are called the **vestibular apparatus** (see Fig. 43-8b). Destruction of these organs leads to a considerable loss of the sense of equilibrium. A pigeon whose vestibular apparatus has been destroyed cannot fly but in time can relearn how to maintain equilibrium by using visual stimuli.

The sensory cells of the saccule and utricle are hair cells similar to those of the lateral line organ (FIG. 43-9). The stereocilia projecting from the hair cells are covered by a gelatinous cupula in which calcium carbonate ear stones, called **otoliths**, are embedded. The hair cells in the saccule and utricle lie in different planes.

Normally, the pull of gravity causes the otoliths to press against the stereocilia, stimulating them to initiate impulses. Sensory neurons at the bases of the hair cells transmit these signals to the brain. When the head is tilted or in

linear acceleration (increasing speed when the body is moving in a straight line), otoliths press on the stereocilia of different cells, deflecting them. Deflection of the stereocilia toward the kinocilium depolarizes the hair cell. Deflection in the opposite direction hyperpolarizes the hair cell. Thus, depending on the direction of movement, the hair cells release more or less neurotransmitter. When the brain interprets the neural messages, the animal becomes aware of its full body position relative to the ground regardless of how its head is positioned.

Information about turning movements, referred to as angular acceleration, is provided by the three semicircular canals. Each canal, a hollow ring connected with the utricle, lies at right angles to the other two. Each canal is filled with fluid called **endolymph**. At one of the openings of each canal into the utricle there is a small, bulblike enlargement, the **ampulla**. Within each ampulla there is a clump of hair cells called a *crista* (pl., *cristae*), similar to the groups of hair cells in the utricle and saccule. No otoliths are present. The stereocilia of the hair cells of the cristae are stimulated by movements of the endolymph in the canals (FIG. 43-10).

When the head is turned, there is a lag in the movement of the fluid within the canals. The stereocilia move in relation to the fluid and are stimulated by its flow. This stimulation produces not only the consciousness of rotation but also certain reflex movements in response to it. These reflexes cause the eyes and head to move in a direction opposite that of the original rotation. Because the three canals are in three different planes, head movement in any direction stimulates fluid movement in at least one of the canals.

We humans are used to movements in the horizontal plane but not to vertical movements (parallel to the long axis of the upright body). The motion of an elevator or of a ship pitching in a rough sea stimulates the semicircular canals in an unusual way and may cause seasickness or motion sickness, with resultant nausea or vomiting. When a seasick person lies down, the movement stimulates the semicircular canals in a more familiar way, and nausea is less likely to occur.

Key Point

The utricle and saccule sense changes in the position of the head relative to gravity as well as changes in the rate of motion when moving in a straight line.

Figure 43-9 The saccule and utricle: maintaining equilibrium

The saccule and utricle sense linear acceleration, allowing us to know our position relative to the ground. Compare the positions of the otoliths and hair cells in (a) with those in (b). Changes in head position cause the force of gravity to distort the cupula, which in turn distorts the stereocilia of the hair cells. The hair cells respond by releasing neurotransmitters. Impulses are transmitted along the vestibulocochlear nerve to the brain.

PREDICT How would the utricle and saccule function in sensing changes in head position under gravity-free (weightless) conditions?

Auditory receptors are located in the cochlea

Many arthropods and most vertebrates have sound receptors, but for many of them hearing does not seem to be a sensory priority. It is important in tetrapods, however, and both birds and mammals have a highly developed sense of hearing. Their auditory receptors are located in the **cochlea** of the inner ear. These mechanoreceptors contain hair cells that detect pressure waves.

The cochlea is a spiral tube that resembles a snail's shell (FIG. 43-11). If the cochlea were uncoiled, you would see that it consists of three canals separated from one another by thin membranes. The canals come almost to a point at the apex. Two of these canals, the *vestibular canal* and the *tympanic canal*, connect at the apex of the cochlea and are filled with a

fluid called *perilymph*. The middle canal, the *cochlear duct*, is filled with endolymph. The cochlear duct contains the auditory organ, the **organ of Corti**.

The organ of Corti contains about 18,000 hair cells in rows that extend the length of the coiled cochlea. The stereocilia of each hair cell extend into the cochlear duct. The hair cells rest on the **basilar membrane**, which separates the cochlear duct from the tympanic canal. Another membrane, the **tectorial membrane**, overhangs and is in contact with the hair cells.

Sound waves are amplified in the middle ear In terrestrial vertebrates, sound waves in the air are transformed into pressure waves in the cochlear fluid. In the human ear, for example, sound waves pass through the *external auditory canal* and

Key Point

The semicircular canals detect angular acceleration or deceleration of the head (changes in the position of the head when you are turning it).

Figure 43-10 Semicircular canals and equilibrium

When the head changes its rate of rotation, endolymph within the ampulla of the semicircular canal distorts the cupula. The stereocilia of the hair cells bend, increasing the frequency of action potentials in sensory neurons. Information is transmitted to the brain via the vestibular nerve.

PREDICT A child spinning in a circle becomes dizzy. The child is advised to spin a few times in the opposite direction. What effect would this have? Explain.

vibrate the **tympanic membrane**, or eardrum, which separates the outer ear and the middle ear. The vibrations are transmitted across the middle ear by three tiny bones: the **malleus**, **incus**, and **stapes** (or hammer, anvil, and stirrup, so called because of their shapes). The malleus is in contact with the eardrum, and the stapes is in contact with a thin, membranous region of the cochlea called the **oval window**. The **eustachian tube**, which connects the middle ear with the pharynx (throat region), helps equalize pressure between the middle ear and the atmosphere.

The malleus, incus, and stapes act as three interconnected levers that amplify vibrations. A small movement in the malleus causes a larger movement in the incus and a very large

movement in the stapes. The vibrations pass through the oval window to the perilymph in the vestibular canal. If sound waves were conducted directly from air to the oval window, much energy would be lost. The middle ear functions to couple sound waves in the air with the pressure waves conducted through the fluid in the cochlea.

Because liquids cannot be compressed, the oval window could not cause movement of the fluid in the vestibular canal if there were no escape valve for the pressure. This valve is provided by the membranous **round window** at the end of the tympanic canal. The pressure wave presses on the membranes separating the three ducts and is transmitted to the tympanic canal. The pressure wave makes the round window bulge. The movements of the basilar membrane produced by these pulsations cause the stereocilia of the organ of Corti to rub against the overlying tectorial membrane.

Stereocilia are bent by their contact with the tectorial membrane. As a result, ion channels in the plasma membrane of the hair cells open. Calcium ions move into the hair cell, causing the release of glutamate. This neurotransmitter binds to receptors on sensory neurons that synapse with each hair cell, leading to depolarization of these sensory neurons. Axons of the sensory neurons join to form the **cochlear nerve**, a component of the vestibulocochlear nerve (cranial nerve VIII; also referred to as the **auditory nerve**).

We can summarize the sequence of events involved in hearing as follows:

sound waves enter external auditory canal → tympanic membrane vibrates → malleus, incus, and stapes amplify vibrations → oval window vibrates → vibrations are conducted through fluid → basilar membrane vibrates → hair cells in organ of Corti are stimulated → cochlear nerve transmits impulses to brain

Sounds differ in pitch, loudness, and tone quality

Pitch depends on frequency of sound waves, or number of vibrations per second, and is expressed in hertz (Hz). Low-frequency vibrations result in the sensation of low pitch, whereas high-frequency vibrations result in the sensation of high pitch. Sounds of a given frequency set up resonance waves in the cochlear fluid that cause a particular section of the basilar membrane to vibrate. The brain infers the pitch of a sound from the particular hair cells that are stimulated.

The human ear typically registers sound frequencies between about 20 and 20,000 Hz (also expressed as 20 kilohertz) and is most sensitive to sounds between 1000 and 4000 Hz (**FIG. 43-12**). Comparing the energy of audible sound waves with the energy of visible light waves, your ear is ten times more sensitive than your eye. Dogs can hear sounds up to 40,000 Hz, and bats can detect frequencies as high as 100,000 Hz.

Loud sounds cause resonance waves of greater amplitude (height). The hair cells are more intensely stimulated, and the cochlear nerve transmits a greater number of impulses per second. Variations in tone quality (timbre)—such as when an

Key Point

The hair cells in the organ of Corti in the cochlea are the receptors for hearing.

Figure 43-11 The cochlea, organ of hearing

PREDICT Imagine that the hair cells at one end of the organ of Corti were damaged and could no longer be stimulated by the tectorial membrane. How would that affect hearing?

oboe, a cornet, and a violin play the same note—depend on the number and kinds of overtones, or harmonics, produced. Many hair cells along the basilar membrane are stimulated and vibrate simultaneously in addition to the main vibration common to all three instruments. Thus, differences in

tone quality are recognized in the pattern of the hair cells stimulated.

Deafness may be caused by injury to, or malformation of, either the sound-transmitting mechanism of the outer, middle, or inner ear or the sound-perceiving mechanism of the

Figure 43-12 Distinguishing pitch

The basilar membrane is shown here coiled as it would be within the cochlea. Various parts of the basilar membrane vibrate in response to specific frequencies. The narrow, stiff end of the basilar membrane responds to higher frequencies, whereas the wide, flexible end responds to lower frequencies. Pitch depends on frequency of sound waves expressed as hertz (Hz). The human ear is most sensitive to sounds between 1000 and 4000 Hz (darker pink).

inner ear. Efferent neurons from the brain stem protect the hair cells of the organ of Corti by dampening their response. Even so, exposure to high-intensity sound, such as heavily amplified music, damages hair cells in the organ of Corti.

- List the sequence of events involved in hearing.

43.6 Chemoreceptors

🎯 LEARNING OBJECTIVE

- 9 Compare the structure and function of the receptors of taste and smell, and describe the function of the vomeronasal organ.

The mechanisms for chemoreception have been highly conserved throughout the animal kingdom. Two highly sensitive types of **chemoreceptors** evolved: one for taste, more formally called *gustation*, and one for smell, or *olfaction*. These chemical senses, found throughout the animal kingdom, allow animals to detect chemical substances in food, water, and air. Evaluating such chemical cues allows animals to find food and mates and to avoid predators. Members of the same species use chemoreception to communicate about these critical issues.

For terrestrial vertebrates, the sense of smell involves gaseous substances, called *odorants*, that reach olfactory receptors through the air. The sense of taste depends on sensing chemicals called *tastants*, dissolved in water (or saliva) in the mouth. For aquatic animals, these distinctions blur. Does a catfish smell or taste the water?

The organs of taste and smell in insects are sensory hairs called *sensilla* (sing., *sensillum*) that project from the cuticle. Olfactory sensilla are typically found on the antennae. In some insects, including ants, bees, and wasps, taste sensilla are also located on the antennae. Taste sensilla typically project from the mouthparts. In butterflies and flies, they may also project from the end of the leg.

In the blowfly each sensillum contains four chemoreceptors (FIG. 43-13). Dendrites from each cell extend to an opening at the tip, and axons transmit sensory signals to the brain. Studies suggest that insects can distinguish among various

Figure 43-13 An insect taste receptor

Insects respond to a wide variety of chemical substances found in foods. Each sensillum in the blowfly contains four chemoreceptors. Dendrites that extend to an opening at the tip sense taste. The other end of each chemoreceptor is an axon that transmits sensory signals to the brain.

bitter tastes more precisely than mammals can. This ability is important in discriminating tastes associated with spoiled, bacteria-laden foods or toxins.

Taste receptors detect dissolved food molecules

As just described for insects, the ability to discriminate among tastes has survival value. Poisons are generally bitter. In contrast, foods with a high caloric value often taste sweet. Mammals sense taste with *taste buds* located in the mouth.

In humans, taste buds lie mainly in tiny elevations, or papillae, on the tongue. Each of the 10,000 or so taste buds is an oval epithelial capsule containing about 50 taste receptor cells interspersed with supporting cells (**FIG. 43-14**). Taste receptor cells are replaced about every ten days. One sensory neuron can innervate several taste buds. The plasma membrane at the tip of each taste receptor cell has microvilli that extend into a taste pore on the surface of the tongue, where they are bathed in saliva. The taste receptors detect tastants dissolved in saliva.

Although mammals can sense thousands of different tastes, most tastes are thought to be combinations of five basic tastes: sweet, sour, salty, bitter, and umami (the Japanese word for delicious). Umami is responsible for the savory flavor of certain aged cheeses, soy sauce, anchovies, and some types of seafood. The amino acid glutamate is the compound

that triggers the taste. In the form of its sodium salt, monosodium glutamate, or MSG, this compound is used to flavor foods. Additional basic tastes have been proposed, including *fatty*, which is stimulated by fatty acids.

The process of tasting sweet, bitter, or umami involves a signal transduction process in which glucose, or another tastant, binds to a G protein-linked receptor that activates a second messenger system (see Chapter 6). Salty and sour tastants act directly on ion channels. In each case, action potentials are generated. Signals are transmitted (by way of the brain stem and thalamus) to the gustatory area in the parietal lobe as well as to the limbic system.

Flavor depends on the basic tastes in combination with smell, texture, and temperature. Smell affects flavor because odors pass from the nasal chamber to the mouth. You have probably observed that when your nose is congested, food seems to have little “taste.” The taste buds are not affected, but the blockage of nasal passages severely reduces the participation of olfactory reception in the composite sensation of flavor.

The olfactory epithelium is responsible for the sense of smell

Most invertebrates and some vertebrates (e.g., rodents) depend on olfaction, the detection of odors, as their main sensory modality. In terrestrial vertebrates olfaction occurs in the nasal epithelium.

In humans the **olfactory epithelium** is found in the roof of the nasal cavity (**FIG. 43-15**). It contains about 100 million olfactory receptor cells with ciliated tips. Each receptor cell is actually an axon. The long, nonmotile cilia extend into a layer of mucus on the epithelial surface of the nasal passageway. Receptor molecules on the cilia bind with compounds dissolved in the mucus. Remarkably, the olfactory receptor cells are replaced about every two months in humans, yet another example of the generation of new neurons throughout life.

The olfactory receptor cell axons project directly to the brain. These axons make up the **olfactory nerve** (cranial nerve I), which extends to the **olfactory bulb** in the brain. From there, information is transmitted to the *olfactory cortex* in the limbic system. Recall that the limbic system is also associated

Figure 43-14 Chemoreception: taste

Figure 43-15 Chemoreception: olfaction

Many animals communicate with pheromones

Animals within many species communicate with one another by releasing **pheromones**, small, volatile molecules that are secreted into the environment. For example, female moths release pheromones that attract males. Dogs and wolves use pheromones to mark territory.

Mammals have specialized chemoreceptor cells that detect pheromones. These cells make up the **vomer nasal organ** located in the epithelium of the nose (separate from the main olfactory epithelium). The vomeronasal sensory neurons send signals to areas of the hypothalamus, which serves as a link with the endocrine system. (We discuss pheromones further in Chapter 52.)

with emotions. Odors are often associated with feelings and memories.

When an *odorant*, a molecule that can be smelled, binds with a receptor on a cilium of an olfactory receptor cell, a signal transduction process is initiated. A G protein is activated, leading to the synthesis of cyclic AMP, which opens ion channels in the plasma membrane. These channels permit Na^+ and Ca^{2+} to enter the cell, causing depolarization. Calcium-gated chloride channels then open, and Cl^- move out of the cell, causing further depolarization. The number of odorous molecules determines the intensity, which in turn determines the magnitude of the receptor potential. The receptor potential generates action potentials in the afferent neuron.

Humans and chimps have about 400 functional olfactory genes, each coding for an olfactory receptor protein. In contrast, dogs have about 1000 functional olfactory genes.

The combination of receptors activated determines the odors perceived. Humans are capable of perceiving about 10,000 scents. Interestingly, studies have shown that dogs can be trained to detect patients with certain types of cancer based on scent.

The olfactory receptors respond to remarkably small amounts of a substance. For example, most people can detect ionone, the synthetic substitute for the odor of violets, when it is present in a concentration of only 1 part to more than 30 billion parts of air. Smell is perhaps the sense that adapts most quickly. The olfactory receptors adapt about 50% in the first second or so after stimulation, so even air that smells awful may seem odorless after only a few minutes.

CHECKPOINT 43.6

- **CONNECT** In what ways are olfaction and gustation similar?

43.7 Photoreceptors

LEARNING OBJECTIVES

- 10 Contrast simple eyes, compound eyes, and vertebrate eyes.
- 11 Identify each structure of the vertebrate eye and describe its function.
- 12 Compare the two types of photoreceptors, describe the signal transduction pathway that is activated when rhodopsin responds to light, and summarize the visual pathway.

Most animals have **photoreceptors** that use pigments to absorb light energy. **Rhodopsins** are the photopigments in the eyes of cephalopod mollusks (squids and octopods), arthropods, and vertebrates. Light energy striking a light-sensitive receptor cell containing these pigments triggers chemical changes in the pigment molecules that result in receptor potentials.

Invertebrates have several types of light-sensing organs

The simplest light-sensitive structures in animals are found in certain cnidarians and flatworms (FIG. 43-16). They are **eyespots**, also called **ocelli**, which detect light but do not form images. Eyespots are often bowl-shaped clusters of light-sensitive cells within the epidermis. They may detect the direction of the light source and distinguish light intensity.

Figure 43-16 Photoreception: eyespots

The simplest light-sensitive structures are the ocelli, or eyespots, found in certain invertebrates.

Effective image formation requires a more complex *eye*, usually with a *lens*. A *lens* concentrates light on a group of photoreceptors. Vision also requires a brain that can interpret the action potentials generated by the photoreceptors. The brain integrates information about movement, brightness, location, position, and shape of the visual stimulus. Two fundamentally different types of eyes evolved: the compound eye of arthropods and the camera eye of vertebrates and cephalopod mollusks.

The **compound eyes** of crustaceans and insects differ structurally and functionally from vertebrate eyes. The surface of a compound eye appears faceted, which means “having many faces,” like a diamond (FIG. 43-17). Each *facet* is the convex *cornea* of one of the eye’s visual units, called **ommatidia** (sing., *ommatidium*). The number of ommatidia varies with the species. For example, each eye of certain crustaceans has only 20 ommatidia, whereas the dragonfly eye has as many as 28,000!

The optical part of each ommatidium includes a biconvex lens and a *crystalline cone*. The lens and crystalline cone focus light onto photoreceptor cells called **retinular cells**. These cells have a light-sensitive membrane made up of microvilli that contain rhodopsin. The membranes of several retinular cells may fuse to form a central rod-shaped *rhabdome* that is sensitive to light.

Compound eyes do not perceive form well. Although the lens system of each ommatidium is adequate to focus a small inverted image, there is little evidence that the animal actually perceives them as images. However, all the ommatidia together produce a composite image, or *mosaic* picture. In gathering a point of light from a narrow sector of the visual field, each ommatidium is, in fact, sampling a mean intensity from that sector. All these points of light taken together form a mosaic picture (see Fig. 43-17d).

Arthropod eyes usually adapt to different intensities of light. A sheath of pigmented cells envelops each ommatidium, and screening pigments are present in *iris cells* and retinular cells. In nocturnal and crepuscular (active at dusk) insects and many crustaceans, pigment migrates proximally and distally within each pigmented cell. When the pigment is in the proximal position, each ommatidium is shielded from its neighbor, and only light entering directly along its axis can stimulate the receptors. When the pigment is in the distal position, light striking at any angle can pass through several ommatidia and stimulate many retinal units. As a result, sensitivity is increased in dim light, and the eye is protected from excessive stimulation in bright light. Pigment migration is under neural control in insects and under hormonal control in crustaceans. In some species it follows a daily rhythm.

Although the compound eye can form only coarse images, it compensates by superbly detecting movement. Flies can detect up to about 265 flickers per second. In contrast, the human eye can detect only 45 to 53 flickers per second; for us, flickering lights fuse above these values, so we see light provided by an ordinary bulb as steady and the movement in motion pictures as smooth.

To an insect, both room lighting and motion pictures must flicker horribly. The insect’s high critical flicker fusion threshold permits immediate detection of even slight movement by prey or enemy. The compound eye is an important adaptation to the arthropod’s way of life.

Compound eyes differ from our eyes in another respect. They are sensitive to wavelengths of light in the range from red to ultraviolet (UV). Accordingly, an insect can see UV light well, and its world of color is very different from ours. Because they reflect UV light to various degrees, flowers that appear identically colored to humans may appear strikingly dissimilar to insects (see Fig. 37-4g).

Cephalopod mollusks (squids and octopods) and vertebrates have eyes that work somewhat like an old-fashioned camera (described in the next section). Interestingly, the camera eye also evolved in Cubozoa (box jellyfish), a group of cnidarians.

Vertebrate eyes form sharp images

The position of the eyes in the front of the head of primates and certain birds allows both eyes to focus on the same object. The overlap in information they receive results in the same visual information striking the two retinas (light-sensitive areas) at the same time. This *binocular vision* is important in judging distance and in depth perception.

The vertebrate eye can be compared to an old-fashioned camera. An adjustable lens can be focused for different distances, and a diaphragm, called the **iris**, regulates the size of the **pupil**, an opening through which light passes (FIG. 43-18). The **retina** corresponds to the light-sensitive film used in a

(a) SEM of fruit fly (*Drosophila* sp.) showing its prominent compound eyes.

(b) Structure of compound eye showing several ommatidia. The eye registers changes in light and shade, permitting the animal to detect movement.

(c) Structure of an ommatidium. The rhabdome is the light-sensitive core of the ommatidium.

(d) A bee's-eye view of a flower. This photograph was taken using an optical device to achieve an approximate simulation of how the bee might see this flower. However, the bee would see UV light rather than red, and circles would be vertically elongated ellipses.

Figure 43-17 Photoreception: compound eyes

camera. Outside the retina is the **choroid layer**, a sheet of cells filled with black pigment that absorbs extra light. This mechanism prevents light from being reflected back into the photoreceptors, which would cause blurring of images. (Cameras are also black on the inside.) The choroid is rich in blood vessels that supply the retina.

The outer coat of the eyeball, called the **sclera**, is a tough, opaque, curved sheet of connective tissue. The sclera protects the inner structures and helps maintain the rigidity of the eyeball. On the front surface of the eye, this sheet becomes the thinner, transparent **cornea** through which light enters. The cornea serves as a fixed *lens* that focuses light.

The **lens** of the eye is a transparent, elastic ball just behind the iris. It bends the light rays coming in and brings them to

a focus on the retina. The lens is aided by the curved surface of the cornea and by the refractive properties (ability to bend light rays) of the liquids inside the eyeball. The *anterior cavity* between the cornea and the lens is filled with a watery substance, the aqueous fluid. The larger *posterior cavity* between the lens and the retina is filled with a more viscous fluid, the **vitreous body**. By providing an internal hydrostatic pressure, both fluids help maintain the shape of the eyeball.

At its anterior margin, the choroid is thick and projects medially into the eyeball, forming the *ciliary body*, which consists of ciliary processes and the ciliary muscle. The ciliary processes are glandlike folds that project toward the lens and secrete the aqueous fluid.

The eye has the ability to change focus for near or far vision by changing the shape of the lens (**FIG. 43-19**). This process, called **accommodation**, depends on the *ciliary muscle*, a circular muscle that is part of the ciliary body. To focus on close objects, the ciliary muscle contracts, making the elastic lens rounder. To focus on more distant objects, this muscle relaxes and the lens assumes a flattened (ovoid) shape.

The amount of light entering the eye is regulated by the iris, a ring of smooth muscle that appears as blue, green, gray, or brown depending on the amount and nature of pigment present. The iris consists of two mutually antagonistic sets of muscle fibers. One set is arranged circularly and contracts to *decrease* the size of the pupil. The other is arranged radially and contracts to *increase* the size of the pupil.

Each eye also has six muscles that extend from the surface of the eyeball to various points in the bony socket. These muscles enable the eye as a whole to move and be oriented in a given direction. Cranial nerves innervate the muscles in such a way that the eyes normally move together and focus on the same area.

Figure 43-18 Photoreception: structure of the human eye

Light passes through the human eye to photoreceptor cells in the retina. In this lateral view, the eye is shown partly sectioned along the sagittal plane to expose its internal structures.

The retina contains light-sensitive rods and cones

The light-sensitive structure in the vertebrate eye is the retina, which lines the posterior two-thirds of the eyeball and covers the choroid. The retina, which is composed of ten layers, contains the photoreceptor cells called, according to shape, **rods** and **cones**. In both rod and cone cells, infoldings

of the plasma membrane form stacks of membranous discs that contain the photopigments. The discs greatly increase the light-absorbing surface.

The human eye has about 125 million rods and 6.5 million cones. Rods function in dim light, allowing us to detect shape and movement. They do not discriminate among colors. Because the rods are more numerous in the periphery of the retina, you can see an object better in dim light if you look slightly to one side of it (allowing the image to fall on the rods).

Cones respond to light at higher levels of intensity, such as daylight, and they allow us to perceive fine detail. Cones are responsible for color vision; they are differentially sensitive to different wavelengths (colors) of light. In primates and certain hunting birds (such as eagles), the cones are most concentrated in the fovea, a small, depressed area in the center of the retina. The **fovea** is the region of sharpest vision because it has the greatest density of receptor cells and because the retina is thinner there.

Light must pass through several layers of connecting neurons in the retina to reach the rods and cones (**FIG. 43-20**). This arrangement lets the rods and cones contact a layer of pigmented epithelium that provides **retinal**, a component of rhodopsin. The retina has five main types of neurons. (1) Photoreceptors (rods and cones) synapse on (2) **bipolar cells**, which make synaptic contact with (3) **ganglion cells**. Two types of lateral interneurons are the (4) **horizontal cells**, which receive information from the photoreceptor cells and send it to bipolar cells, and the (5) **amacrine cells**, which receive messages from the bipolar cells and send signals back to them or to ganglion cells (**FIG. 43-21**).

Figure 43-19 Accommodation

How the eye changes focus for (a) near and (b) distant vision.

Key Point

The rods and cones in the retina are the photoreceptors in vertebrates.

(a) Neurons in the retina. The elaborate interconnections among the various layers of neurons in the retina allow them to interact and influence one another.

(b) SEM of rods and cones. The *tan*, elongated structures are rods. The shorter, thicker, *green* structures are cones. The rods function in dim light and allow you to see shapes and movement. The cones allow you to view the world in color.

Horizontal and amacrine cells help process visual input within the retina. Interestingly, one group of ganglion cells *project* to (i.e., have axons that extend to) the *suprachiasmatic nucleus*, the body's main biological clock. These ganglion cells contain a light-sensitive pigment (melanopsin) that is important in nonvisual responses to light.

The axons of the ganglion cells extend across the surface of the retina and unite to form the **optic nerve**. The area where the optic nerve passes out of the eyeball, the *optic disk*, is known as the *blind spot*; because it lacks rods and cones, images falling on it cannot be perceived.

Here is a simplified summary of the visual pathway:

light passes through cornea → through aqueous fluid → through lens → through vitreous body → image forms on photoreceptor cells in retina → signal bipolar cells → signal ganglion cells → optic nerve transmits signals to thalamus → integration by visual areas of cerebral cortex

Light activates rhodopsin

How is light converted into the neural signals that transmit information about environmental stimuli into pictures in the brain? Rod cells are so sensitive to light that they can respond to a single photon. Rhodopsin in the rod cells and some very closely related photopigments in the cone cells are responsible for the ability to see. **Rhodopsin** consists of *opsin*, a large protein that is chemically joined with *retinal*, an aldehyde of vitamin A (see Fig. 3-14). Two isomers of retinal exist: the *cis* form, which is folded, and the *trans* form, which is straight.

In the dark, opsin binds to retinal in the *cis* form. Cyclic GMP (cyclic guanosine monophosphate, a molecule similar to cyclic AMP) opens nonspecific channels that permit passage of Na^+ and other cations into the rod cell (**FIG. 43-22**). This process depolarizes the rod cell, which then releases the neurotransmitter glutamate. The glutamate is inhibitory; it hyperpolarizes the membrane of the bipolar cell, preventing it from transmitting messages.

Note that the photoreceptor differs from other neurons in that the ion channels in its membrane are normally open; it is depolarized and continuously releases inhibitory neurotransmitter. The steady flow of ions into the cell when the environment is dark is called the *dark current*. Another unusual characteristic of photoreceptors, and of bipolar cells, is that they do not produce action potentials.

Figure 43-20 Organization of the retina

CONNECT Why is it difficult to see colors in dim light?

Figure 43-21 Neural pathway in the retina

The photoreceptor cells (rods and cones) are located in the back of the retina. They transmit information to bipolar cells. The bipolar cells synapse with ganglion cells. The horizontal and amacrine cells are important in local processing of visual input within the retina. Axons of ganglion cells make up the optic nerve.

Their release of neurotransmitter is graded, regulated by the extent of depolarization.

When light strikes rhodopsin, light energy is transduced. This process can be considered in three stages:

1. **Light activates rhodopsin.** Light transforms *cis*-retinal to *trans*-retinal. Rhodopsin changes shape and breaks down into its components: opsin and retinal. This sequence is the light-dependent process in vision.
2. **Rhodopsin activates a signal transduction pathway.** When it changes shape, rhodopsin binds with *transducin*, a G protein. Transducin activates an esterase that hydrolyzes cyclic GMP (cGMP) to GMP, reducing the concentration of cGMP.

3. **A decrease in concentration of cGMP in the rod causes the Na^+ channels to close.** Fewer cations pass into the rod cell, and it becomes more negative (hyperpolarized). The rod cell then releases less glutamate. Thus, light decreases the number of neural signals from the rod cells.

The release of glutamate normally hyperpolarizes the membrane of the bipolar cell, so a decrease in glutamate release results in depolarization of the bipolar cell. The depolarized bipolar cell increases its release of a neurotransmitter, which typically stimulates the ganglion cell.

When you move from bright daylight to a dark room, you experience “blindness” for a few moments while your eyes adapt. During exposure to bright light, rhodopsin breaks down, decreasing the sensitivity of your eyes. *Dark adaptation* occurs as enzymes restore rhodopsin to a form in which it can respond to light. In dim light, vision depends on the rods. Conversely, when you move from the dark to bright light, your eyes are very sensitive, and you may feel “blinded” by the light. *Light adaptation* occurs as some of the photopigments break down and the sensitivity of your eyes decreases.

Color vision depends on three types of cones

Many invertebrates and at least some animals in each vertebrate class have color vision. Color perception depends on cones. Most mammals have two types of cones, but humans and other primates have three types: blue, green, and red. Each contains a slightly different photopigment. Although the retinal portion of the pigment molecule is the same as in rhodopsin, the opsin protein differs slightly in each type of photoreceptor.

Each type of cone responds to light within a considerable range of wavelengths but is named for the ability of its pigment to absorb a particular wavelength more strongly than other cones do. For example, red light can be absorbed by all three types of cones, but those cones most sensitive to red act as red receptors. By comparing the relative responses of the three types of cones, the brain can detect colors of intermediate wavelengths. Color blindness occurs when there is a deficiency of one or more of the three types of cones. It is usually an inherited X-linked condition (see Fig. 11-15).

Integration of visual information begins in the retina

The size, intensity, and location of light stimuli determine initial processing in the retina. Rods and cones send signals directly to bipolar cells, and bipolar cells send signals directly to ganglion cells. However, as illustrated in Figure 43-21, photoreceptor cells can also transmit signals to horizontal cells, and bipolar cells can transmit signals to amacrine cells. Ganglion cells are inhibited by amacrine cells and can be inhibited indirectly by horizontal cells as a result of their action on bipolar cells. Thus, the horizontal and amacrine cells integrate signals laterally.

Bipolar, horizontal, and amacrine cells combine signals from several photoreceptors. Each ganglion cell has a

Figure 43-22 The biochemistry of vision

Inward foldings of the plasma membrane produce a series of discs in each rod cell. In the dark, the rod cell is depolarized; in the light, it becomes hyperpolarized.

receptive field, a specific group of photoreceptors that light must strike for the ganglion cell to be stimulated. Ganglion cells are activated or inhibited depending on which photoreceptor cells have been stimulated.

The pattern of neuron firing in the retina is very important. The signals sent to ganglion cells depend on spatial patterns and timing of the light striking the retina. Ganglion cells receive signals about specific types of visual stimuli, such as color, brightness, and motion, and transmit this information about the characteristics of a visual image. In contrast with rods and cones and most other neurons of the retina, which produce only graded potentials, ganglion cells produce action potentials.

The retina begins the construction of visual images, but those images are interpreted in the brain. Axons of more than one million ganglion cells form the optic nerves. These cranial nerves transmit information to the brain by complex, encoded signals. Axons from the medial half of each retina cross to the opposite side in the floor of the hypothalamus, forming an X-shaped structure, the **optic chiasm** (FIG. 43-23). The axons of the *optic nerves* that cross over extend to the opposite side of the brain.

Axons of the *optic nerves* end in the *lateral geniculate nuclei* of the thalamus. From there, neurons send signals to the

primary visual cortex in the occipital lobe of the cerebrum. The lateral geniculate nucleus controls what information is sent to the visual cortex. Neurons in the reticular activating system are involved in this integration. Information is transmitted from the primary visual cortex to other cortical areas for further processing.

Different types of ganglion cells receive information about different aspects of a visual stimulus. As a result, information from each point in the retina is transmitted in parallel by several types of ganglion cells. These cells project to different kinds of neurons in the lateral geniculate nucleus and primary visual cortex.

Neurobiologists have not yet discovered all the mechanisms by which the brain makes sense of the visual information it receives. We know that a large part of the association areas of the cerebrum is involved in integrating visual input. The neurons of the visual cortex are organized as a map of the external visual field. They are also organized into columns. Each column of neurons receives signals originating from light entering either the right or the left eye. Columns are also organized by orientation of light. Neurons in a column receive signals originally triggered by light with the same orientation. However, these signals originate from different locations in the retina.

Figure 43-23 Neural pathway for transmission of visual information

Axons of ganglion cells form the optic nerves. In the brain, fibers from the medial half of each retina cross to the opposite side, forming the optic chiasm. Many optic nerve fibers end in the lateral geniculate nuclei of the thalamus. From there, signals are sent to the visual area in the occipital lobe. (Brain is viewed from above with overlying structures removed.)

CHECKPOINT 43.7

- **CONNECT** How does the insect's compound eye compare with the vertebrate eye?
- What happens when light strikes rhodopsin? (Include a description of the signal transduction pathway in your answer.)
- What is the sequence of neural signaling in the retina?
- What is meant by the statement "Vision happens mainly in the brain"?

Summary: Focus on Learning Objectives

43.1 How Sensory Systems Work (page 912)

1 Describe how sensory systems function; include descriptions of sensory receptors, energy transduction, receptor potential, sensory adaptation, and perception.

- **Sensory receptors** are neuron endings or specialized receptor cells in close contact with neurons. **Sense organs** consist of sensory receptors and accessory cells.
- A sensory receptor absorbs energy from a stimulus and transduces that energy—*energy transduction*—into electrical energy. In response to stimuli, a sensory receptor produces **receptor potentials**, which are depolarizations or hyperpolarizations of the membrane. Receptor potentials are **graded potentials**, local changes in electrical potential that vary in magnitude depending on the strength of the stimulus. Receptor potentials can generate action potentials in **sensory neurons**, which transmit coded signals to the CNS.
- **Sensory adaptation**, the decrease in frequency of action potentials in a sensory neuron even when the stimulus is maintained, decreases response to that stimulus.
- The brain interprets sensations by converting them to perceptions of stimuli. Sensory **perception** is the process of selecting, interpreting, and organizing sensory information.

2 Classify sensory receptors according to the location of the stimuli to which they respond and according to the types of energy they transduce.

- **Exteroceptors** receive stimuli from the outside environment. **Interoceptors** detect changes within the body, such as changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood.

- Sensory receptors can be classified according to the types of energy they transduce. *Thermoreceptors* respond to heat and cold. *Electroreceptors* sense differences in electrical potential. *Nociceptors* (pain receptors) respond to mechanical stimuli, temperature, and other stimuli that could be damaging. *Mechanoreceptors* transduce mechanical energy: touch, pressure, gravity, stretching, and movement. *Chemoreceptors* transduce certain chemical compounds, and photoreceptors transduce light energy.

43.2 Thermoreceptors (page 915)

3 Identify three functions of thermoreceptors.

- **Thermoreceptors** transduce thermal energy; they respond to heat and cold. Some parasites use thermoreceptors to find an endothermic host. Some predators use thermoreceptors to locate endothermic prey. In endothermic animals, thermoreceptors provide cues about body temperature.

43.3 Electroreceptors and Magnetic Reception (page 916)

4 Describe the functions of electroreceptors and identify the functions of magnetic reception.

- **Electroreceptors** respond to electrical stimuli. Predatory fishes use electroreceptors to detect prey.
- Some animals detect and use information about Earth's magnetic fields to orient themselves. Many migratory animals use magnetic fields to navigate.

43.4 Nociceptors (page 916)

5 Describe the functions of nociceptors and identify the roles of substance P and endorphins.

- **Nociceptors** are pain receptors; they are free nerve endings of certain sensory neurons that respond to strong tactile stimuli, temperature extremes, and certain chemicals. Sensory neurons that transmit pain signals release **substance P** or **glutamate**. **Endorphins** and **enkephalins** inhibit release of substance P, ending transmission of the pain signal.

43.5 Mechanoreceptors (page 916)

- 6 Compare the functions and mechanisms of action of the following mechanoreceptors: tactile receptors, proprioceptors, statocysts, hair cells, and lateral line organs.
 - **Mechanoreceptors** transduce mechanical energy, permitting animals to feel, hear, and maintain balance. Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement. They are activated when they change shape as a result of being mechanically pushed or pulled.
 - *Tactile receptors* in the skin respond to mechanical displacement of hairs or to displacement of the receptor cells themselves. The **Pacinian corpuscle** is a tactile receptor that responds to touch and pressure.
 - **Proprioceptors** allow an animal to perceive orientation of its body and the positions of its parts. **Muscle spindles**, **Golgi tendon organs**, and **joint receptors** are proprioceptors that continuously respond to tension and movement.
 - **Statocysts**, gravity receptors found in many invertebrates, are simple organs of equilibrium; they inform the CNS of change in position. A statocyst consists of a chamber lined with ciliated mechanoreceptors; the chamber contains **statoliths**, granules of sand grains or calcium carbonate that change position as the animal moves. As statoliths move, sensory hairs bend, and different sensory cells are stimulated.
 - Vertebrate **hair cells** detect movement; they are found in the lateral line of fishes, the vestibular apparatus, semicircular canals, and cochlea. Each hair cell has a single **kinocilium**, which is a true cilium, and **stereocilia**, which are microvilli.
 - **Lateral line organs** supplement vision in fishes and some amphibians by informing the animal of moving objects or objects in its path.
- 7 Compare the structure and function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.
 - The vertebrate *inner ear* consists of a **labyrinth** of fluid-filled chambers and canals that help maintain equilibrium. The **vestibular apparatus** in the upper part of the labyrinth consists of the **saccule**, **utricle**, and **semicircular canals**.
 - The saccule and utricle contain **otoliths**, calcium carbonate ear stones, that change position when the head is tilted or when the body is moving in a straight line. The otoliths stimulate hair cells that send signals to the brain, enabling the animal to perceive the direction of gravity.
 - The semicircular canals inform the brain about turning movements. Clumps of hair cells, called *cristae*, are located within each bulblike enlargement, called an **ampulla**. *Cristae* are stimulated by movements of the **endolymph**, a fluid that fills each canal.
- 8 Trace the path taken by sound waves through the structures of the ear and explain how the organ of Corti functions as an auditory receptor.

- In terrestrial vertebrates, the **organ of Corti** within the **cochlea** contains auditory receptors.
- Sound waves pass through the *external auditory canal* and cause the **tympanic membrane** (eardrum) to vibrate. The ear bones—**malleus**, **incus**, and **stapes**—transmit and amplify the vibrations through the middle ear. Vibrations pass through the *oval window* to fluid within the vestibular canal. Pressure waves press on the membranes that separate the three ducts of the cochlea.
- The bulging of the *round window* serves as an escape valve for the pressure. The pressure waves cause movements of the **basilar membrane**. These movements stimulate the hair cells of the organ of Corti by rubbing them against the overlying **tectorial membrane**.
- Neural impulses are initiated in the dendrites of neurons that lie at the base of each hair cell and are transmitted by the *cochlear nerve* to the brain.

43.6 Chemoreceptors (page 924)

- 9 Compare the structure and function of the receptors of taste and smell, and describe the function of the vomeronasal organ.
 - **Chemoreceptors** transduce certain kinds of chemical compounds, allowing *gustation*, or taste, and *olfaction*, or smell.
 - In vertebrates, taste receptor cells are specialized epithelial cells in *taste buds*. The **olfactory epithelium** contains specialized olfactory receptors with axons that extend to the brain. These axons make up the **olfactory nerve**.
 - Receptors that make up the **vomeronasal organ**, located in the nasal epithelium of mammals, detect **pheromones**, small, volatile signaling molecules released by animals.

43.7 Photoreceptors (page 926)

- 10 Contrast simple eyes, compound eyes, and vertebrate eyes.
 - **Photoreceptors** transduce light energy and serve as the sensory receptors in eyespots and eyes. *Eyespots*, or **ocelli**, found in cnidarians and flatworms, detect light but do not form images.
 - The **compound eye** of insects and crustaceans consists of visual units called **ommatidia**, which collectively produce a *mosaic* image. Each ommatidium has a transparent lens and a *crystalline cone* that focus light onto receptor cells called **retinular cells**.
 - Vertebrates have camera eyes that form sharp images.

11 Identify each structure of the vertebrate eye and describe its function.

- In the human eye, light enters through the **cornea**, passes through the **pupil**, is focused by the **lens**, and produces an image on the **retina**. The **iris** regulates the amount of light that can enter. The internal surface of the eye is covered by the **choroid layer**, a black coat that prevents light rays from scattering.
- **Accommodation** is the process by which the lens changes shape, allowing the eye to focus at various distances. The lens is attached to the circular *ciliary muscle*. When the ciliary muscle contracts, the lens becomes rounder. When it relaxes, the lens flattens.

12 Compare the two types of photoreceptors, describe the signal transduction pathway that is activated when rhodopsin responds to light, and summarize the visual pathway.

- The retina contains the photoreceptor cells: **rods**, which function in dim light and form images in black and white, and **cones**, which function in bright light and permit color vision.
- Rods and cones send signals to **bipolar cells** that send signals to **ganglion cells**. Two types of lateral interneurons integrate information: **horizontal cells** receive signals

from the rods and cones and send signals to bipolar cells, and **amacrine cells** receive signals from bipolar cells and send signals back to bipolar cells and to ganglion cells.

- When the environment is dark, ion channels in the plasma membranes of rod cells are open, and the cells are depolarized; they release glutamate, which hyperpolarizes the membranes of bipolar cells so that they do not send signals.
- When light strikes the photopigment **rhodopsin** in the rod cells, its retinal portion changes shape and initiates a signal transduction process that involves *transducin*. This G protein activates an esterase that hydrolyzes cGMP, reducing its concentration. As a result, ion channels close, and the membrane becomes hyperpolarized. The rod cells release less glutamate, and fewer signals are transmitted. As a result, bipolar cells become depolarized and release the neurotransmitter that stimulates ganglion cells.
- Axons of the ganglion cells extend across the retina and join to make up the **optic nerves**. The optic nerves transmit information to the *lateral geniculate nuclei* in the thalamus. From there, neurons project to the *primary visual cortex* and then to other cortical areas.

Test Your Understanding

Know and Comprehend

1. A sensory receptor absorbs energy from some stimulus. The next step is (a) release of neurotransmitter (b) transmission of an action potential (c) energy transduction (d) transmission of a receptor potential (e) sensory adaptation
2. Which of the following is *not* a correct match? (a) mechanoreceptors—touch, pressure (b) electroreceptors—voltage (c) photoreceptors—light (d) chemoreceptors—extreme temperature (e) nociceptors—pain
3. Which of the following is/are associated with informing the brain about turning movements? (a) semicircular canals (b) saccule (c) lymph (d) otoliths (e) utricle
4. In the process of hearing, the basilar membrane vibrates. Which event occurs next? (a) tympanic membrane vibrates (b) bones in middle ear amplify and conduct vibrations (c) cochlear nerve transmits impulses to organ of Corti (d) hair cells in organ of Corti are stimulated (e) vibrations are conducted to chemoreceptors
5. In the human visual pathway, after light passes through the cornea, it next (a) stimulates ganglion cells (b) passes through the lens (c) sends signals through the optic nerve (d) depolarizes horizontal cells (e) hyperpolarizes rod cells
6. When rhodopsin is activated, it (a) concentrates in bipolar cells (b) transmits more action potentials (c) binds with a G protein (d) sends signals to the lateral geniculate nuclei (e) activates substance P

Apply and Analyze

7. **VISUALIZE** In what sequence does information pass through the following structures in the vertebrate eye: optic nerve, bipolar cells, rods and cones, ganglion cells?
8. **CONNECT** Connoisseurs can recognize many varieties of cheese or wine by “tasting.” How can they do so when there are only a few types of taste receptors?

Evaluate and Synthesize

9. **CONNECT** If all neurons transmit the same type of message, how do you know the difference between sound and light? How are you able to distinguish between an intense pain and a mild one? How are these discriminations adaptive?
10. **EVOLUTION LINK** Proteins known as opsins are present in the photoreceptors of all light-sensitive receptors that have been studied. What does this finding suggest about the relationships of organisms as diverse as flatworms, crayfish, and elephants?
11. **EVOLUTION LINK** Once the ability to produce images evolved, eyes evolved relatively rapidly. Hypothesize why image-forming eyes evolved quickly and are now present in most animals.
12. **SCIENCE, TECHNOLOGY, AND SOCIETY** Cochlear implants bring hearing to many children who are born deaf. The prognosis is best when the device is implanted before the child is three years old (during the early years when language is developed). Many individuals in the deaf community (which consists of individuals born deaf or who are affected by deafness) who communicate with sign language oppose cochlear implants. They do not view the inability to hear as a disability. This perspective raises ethical questions for some families with children who are deaf. Argue for and against cochlear implants for very young children.

For access to MindTap and additional study materials visit www.cengagebrain.com.

44 Internal Transport

Most cells require a continuous supply of nutrients and oxygen and removal of waste products. In very small animals, these metabolic needs are met by simple **diffusion**, the net movement of particles from a region of higher concentration of that specific type of particle to a region of lower concentration as a result of random motion. A molecule can diffuse 1 micrometer (μm) in less than 1 millisecond (msec), so diffusion is adequate over microscopic distances. In invertebrates that are only a few cells thick, diffusion is an effective mechanism for distributing materials to and from the cells. Consequently, many small, aquatic invertebrates have no circulatory system. Fluid between the cells, called **interstitial fluid** or tissue fluid, bathes the cells and provides a medium for diffusion of oxygen, nutrients, and wastes.

The time required for diffusion increases with the square of the distance over which diffusion occurs. A cell that is $10\ \mu\text{m}$ away from its oxygen (or nutrient) supply can receive oxygen by diffusion in about 50 msec, but a cell that is $1000\ \mu\text{m}$ (1 mm) away from its oxygen supply would have to wait several minutes! At this distance, a cell could not survive if it had to depend on diffusion alone. The evolution of specialized **circulatory systems** allowed animals to increase in size and become many cells thick. A circulatory system reduces

KEY CONCEPTS

- 44.1** Arthropods and most mollusks have an open circulatory system in which blood bathes the tissues directly; some invertebrates and all vertebrates have a closed circulatory system in which a heart pumps blood that flows through a continuous circuit of blood vessels.
- 44.2** Vertebrate blood consists of plasma, which transports nutrients, wastes, gases, and hormones; red blood cells, which are specialized to transport oxygen; white blood cells, which defend the body against disease; and platelets, which function in blood clotting.
- 44.3** Three main types of vertebrate blood vessels are arteries, which carry blood away from the heart; capillaries, which are exchange vessels; and veins, which carry blood back toward the heart.
- 44.4** During the evolution of terrestrial vertebrates, adaptations in circulatory system structures separated oxygen-rich blood from oxygen-poor blood.
- 44.5** In amniotes, the pacemaker in the sinoatrial node initiates each heartbeat; one complete heartbeat makes up a cardiac cycle.
- 44.6** Blood pressure depends on cardiac output, blood volume, and peripheral resistance.
- 44.7** Along with the evolution of lungs, a double circulation evolved in vertebrates. The pulmonary circulation connects the heart and lungs, while the systemic circulation delivers oxygen-rich blood to all the tissues and organs of the body.
- 44.8** The vertebrate lymphatic system helps maintain fluid homeostasis by returning interstitial fluid to the blood and defends the body against disease organisms.
- 44.9** Several modifiable risk factors have been identified for cardiovascular disease, which is the leading cause of death in the world.

the distance that needed materials must diffuse. It transports oxygen, nutrients, hormones, and other materials to the interstitial fluid surrounding the cells and removes metabolic wastes. In most animals a circulatory system interacts with every organ system in the body.

The computed tomography (CT) scan shown in the chapter-opening photograph visualizes the human heart and several blood vessels. The human circulatory system, also known as the **cardiovascular system**, is the focus of extensive research because cardiovascular disease is the leading cause of death in the United States and throughout the world.

44.1 Types of Circulatory Systems

LEARNING OBJECTIVE

- 1 Contrast internal transport in animals with no circulatory system, animals with an open circulatory system, and animals with a closed circulatory system.

No specialized circulatory structures are present in sponges, cnidarians (hydras, jellyfish), ctenophores (comb jellies), flatworms, or nematodes (roundworms). In cnidarians the central gastrovascular cavity serves as a circulatory organ as well as a digestive organ (FIG. 44-1a). As the animal stretches and contracts, body movements stir up the contents of the gastrovascular cavity and help distribute nutrients.

(a) In *Hydra* and other cnidarians, nutrients circulate through the gastrovascular cavity and come in contact with the inner layer of body cells. Nutrients diffuse the short distance to the outer layer of cells.

(b) In planarian flatworms, the branched gastrovascular cavity allows nutrients to come within close proximity of most body cells.

Figure 44-1 Invertebrates with no circulatory system

Red arrows indicate the path of nutrient circulation through the gastrovascular cavity.

The flattened body of the flatworm permits effective gas exchange by diffusion (FIG. 44-1b). Its branched gastrovascular cavity brings nutrients close to all the cells. As in cnidarians, circulation is aided by contractions of the body wall muscles, which move the fluid throughout the gastrovascular cavity. The branching excretory system of planarians provides for transport of metabolic wastes that are then expelled from the body.

Fluid in the body cavity of nematodes and other pseudocoelomate animals helps circulate materials. Nutrients, oxygen, and wastes dissolve in this fluid and diffuse through it to and from the cells. Body movements of the animal move the fluid and thus distribute these materials.

Larger animals require a circulatory system to distribute materials efficiently. A circulatory system typically has the following components: (1) **blood**, a connective tissue consisting of cells and cell fragments dispersed in fluid, usually called *plasma*; (2) a pumping organ, generally a **heart**; and (3) a system of **blood vessels** or spaces through which blood circulates. Two main types of circulatory systems are open and closed systems.

Many invertebrates have an open circulatory system

Arthropods and most mollusks have an **open circulatory system** in which the heart pumps blood into vessels that have open ends. Their blood and interstitial fluid are collectively referred to as **hemolymph**. This fluid spills out of the open ends of the blood vessels, filling large spaces called *sinuses*. The sinuses make up the **hemocoel** (blood cavity), which is not part of the coelom. (In arthropods and mollusks, the size of the coelom is reduced.) The hemolymph bathes the cells of the body directly. Hemolymph re-enters the circulatory system through openings in the heart (in arthropods) or through open-ended vessels that lead to the gills (in mollusks).

In the open circulatory system of most mollusks, the heart has three chambers (FIG. 44-2a). The two *atria* receive hemolymph from the gills. The single *ventricle* then pumps the oxygen-rich hemolymph into blood vessels that conduct it into the large sinuses of the hemocoel. After bathing the body cells, the hemolymph passes into vessels that lead to the gills, where it is recharged with oxygen. The hemolymph then returns to the heart.

Some mollusks as well as arthropods have a hemolymph pigment, **hemocyanin**, containing copper that transports oxygen. When oxygenated, hemocyanin is blue and imparts a bluish color to the hemolymph of these animals (the original blue bloods!).

In arthropods a tubular heart pumps hemolymph into arteries, blood vessels that deliver it to the sinuses of the hemocoel (FIG. 44-2b). Hemolymph then circulates through the hemocoel,

(a) In most mollusks, the heart pumps hemolymph into blood vessels that conduct it to the hemocoel. After bathing the cells, the hemolymph enters vessels that conduct it to the gills. The hemolymph is recharged with oxygen and then returned to the heart.

(b) In arthropods, a tubular heart pumps hemolymph into arteries that deliver it to the sinuses of the hemocoel. After circulating, hemolymph re-enters the heart through ostia in the heart wall.

Figure 44-2 Open circulatory systems

In mollusks and arthropods, a heart pumps the blood into arteries that end in sinuses of the hemocoel. Hemolymph circulates through the hemocoel.

eventually returning to the pericardial cavity surrounding the heart. Hemolymph enters the heart through ostia, tiny openings equipped with valves that prevent backflow. The rate of hemolymph circulation increases when the animal moves. Thus, when an animal is active and most needs nutrients for fuel, its own movement ensures effective circulation.

In crayfish and other crustaceans, gas exchange takes place as hemolymph circulates through the gills. However, an open circulatory system cannot provide enough oxygen to maintain the active lifestyle of insects. Hemolymph mainly distributes nutrients and hormones in insects. Oxygen diffuses directly to the cells through a system of air tubes (tracheae) that make up the respiratory system (see Fig. 46-2).

Some invertebrates have a closed circulatory system

Annelids, some mollusks (cephalopods), and echinoderms have a **closed circulatory system** in which blood flows through a continuous circuit of blood vessels. The walls of the smallest

blood vessels, the *capillaries*, are thin enough to permit diffusion of gases, nutrients, and wastes between blood in the vessels and the interstitial fluid that bathes the cells.

Proboscis worms (phylum Nemertea) have a rudimentary closed circulatory system. Their system consists of a complete network of blood vessels but no heart. Blood flow depends on movements of the animal and on contractions in the walls of large blood vessels.

Earthworms and other annelids have a closed circulatory system in which two main blood vessels extend lengthwise in the body (FIG. 44-3). The ventral vessel conducts blood posteriorly, and the dorsal vessel conducts blood anteriorly. Dorsal and ventral vessels are connected by lateral vessels in every segment. Branches of the lateral vessels deliver blood to the surface, where it is oxygenated. In the anterior part of the worm, five pairs of contractile blood vessels (sometimes called “hearts”) connect dorsal and ventral vessels. Contractions of these paired vessels and of the dorsal vessel as well as contraction of the body wall muscles circulate the blood. Earthworms have **hemoglobin**, the same red pigment that transports oxygen in vertebrate blood. However, their hemoglobin is not contained within red blood cells; rather, it is dissolved in the blood plasma.

Although other mollusks have an open circulatory system, the fast-moving cephalopods, such as the squid and octopus, require a more efficient means of internal transport. They have a closed system made even more effective by accessory “hearts” at the base of the gills, which speed passage of blood through the gills.

Vertebrates have a closed circulatory system

The vertebrate circulatory system consists of heart, blood vessels, blood, lymph, lymph vessels, and associated organs such as the thymus, spleen, and liver. All vertebrates have a ventral, muscular

Figure 44-3 Closed circulatory system of the earthworm

Blood circulates through a continuous system of blood vessels. Five pairs of contractile blood vessels deliver blood from the dorsal vessel to the ventral vessel.

heart that pumps blood into a closed system of blood vessels. **Capillaries**, the tiniest blood vessels, have very thin walls that permit exchange of materials between blood and interstitial fluid.

The vertebrate circulatory system performs several functions:

1. Transports nutrients from the digestive system and from storage depots to each cell
2. Transports oxygen from respiratory structures (gills or lungs) to the cells
3. Transports metabolic wastes from each cell to organs that excrete them
4. Transports hormones from endocrine glands to target tissues
5. Helps maintain fluid balance
6. Helps distribute metabolic heat within the body, which helps maintain a constant body temperature in endothermic animals
7. Helps maintain appropriate pH
8. Defends the body against invading microorganisms

CHECKPOINT 44.1

- Compare how oxygen is transported to the body cells in a hydra, flatworm, earthworm, insect, and frog.
- Contrast how an open circulatory system differs from a closed circulatory system.
- What are five functions of the vertebrate circulatory system?

44.2 Vertebrate Blood

LEARNING OBJECTIVES

- 2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets.
- 3 Summarize the sequence of events involved in blood clotting.

In vertebrates, blood consists of a pale yellowish fluid called **plasma** in which red blood cells, white blood cells, and platelets are suspended (FIG. 44-4 and TABLE 44-1). In humans, the total circulating blood volume is approximately 5 L (5.3 qt) in an adult female and about 5.5 L (5.8 qt) in an adult male. About 55% of the blood volume is plasma. The remaining 45% is made up of blood cells and platelets. Because cells and platelets are heavier than plasma, they can be separated from it by centrifugation. Plasma does not separate from blood cells in the body because the blood is constantly mixed as it circulates through the blood vessels.

Plasma is the fluid component of blood

Plasma consists of water (about 92%), proteins (about 7%), salts, and a variety of materials being transported, such as dissolved gases, nutrients, wastes, and hormones. Plasma is in dynamic equilibrium with the interstitial fluid bathing the cells and with the intracellular fluid. As blood passes through the capillaries, substances continuously move into and out

of the plasma. Any deviation from its normal composition signals one or more organs to restore homeostasis.

Plasma contains several kinds of **plasma proteins**, each with specific properties and functions: **fibrinogen**; alpha, beta, and gamma **globulins**; and **albumin**. Fibrinogen is one of the proteins involved in the clotting process. When the proteins involved in blood clotting have been removed from the plasma, the remaining liquid is called **serum**.

Alpha globulins include certain hormones and proteins that transport hormones; prothrombin, a protein involved in blood clotting; and high-density lipoproteins (HDL), which transport fats and cholesterol. Beta globulins include other lipoproteins that transport fats and cholesterol as well as proteins that transport certain vitamins and minerals. The *gamma globulin* fraction of plasma contains many types of antibodies that provide immunity to diseases such as measles and infectious hepatitis. Purified human gamma globulin is sometimes used to treat certain diseases or to reduce the possibility of contracting a disease.

Plasma proteins, especially albumins and globulins, help regulate distribution of fluid between plasma and interstitial fluid. These proteins are too large to pass readily through the walls of blood vessels. They contribute to the blood's osmotic pressure, which helps maintain an appropriate blood volume. Plasma proteins (along with the hemoglobin in the red blood cells) are important acid-base buffers. They help maintain the pH of the blood within a narrow range, near its normal, slightly alkaline pH of 7.4.

Red blood cells transport oxygen

Erythrocytes, informally called **red blood cells (RBCs)**, are highly specialized for transporting oxygen. In most vertebrates, circulating RBCs have nuclei. For example, birds have large, oval, nucleated RBCs. However, in mammals the nucleus is ejected as the RBC develops. Each mammalian RBC is a flexible, biconcave disc 7 to 8 μm in diameter and 1 to 2 μm thick. An internal elastic framework maintains the disc shape and permits the cell to bend and twist as it passes through blood vessels even smaller than its own diameter. Its biconcave shape provides a high ratio of surface area to volume, allowing efficient diffusion of oxygen and carbon dioxide into and out of the cell. In an adult human, about 30 trillion RBCs circulate in the blood, approximately 5 million per μL .

Erythrocytes are produced within the red bone marrow of certain bones: vertebrae, ribs, breastbone, skull bones, and long bones. As an RBC develops, it produces large quantities of **hemoglobin**, the oxygen-transporting pigment that gives vertebrate blood its red color. (Oxygen transport is discussed in Chapter 46.) The lifespan of a human RBC is about 120 days. As blood circulates through the liver and spleen, phagocytic cells remove worn-out RBCs from the circulation. These RBCs are then disassembled, and some of their components are recycled. In the human body, more than 2.4 million RBCs are destroyed every second! As you might imagine, an equal number must be produced in the bone marrow to replace them. Red blood cell production is regulated by the hormone **erythropoietin** (eh-rith'-row-poy'-ih-tin), which the kidneys release in response to a decrease in oxygen.

Figure 44-4 Composition of vertebrate blood

Blood consists of a fluid plasma in which white blood cells, red blood cells, and platelets are suspended.

Anemia is a deficiency in hemoglobin (often accompanied by a decrease in the number of RBCs). When hemoglobin is insufficient, the amount of oxygen transported is inadequate to supply the body's needs. An anemic person may complain of feeling weak and may become easily fatigued. Three general causes of anemia are (1) loss of blood from hemorrhage or internal bleeding; (2) decreased production of hemoglobin or red blood cells, as in iron-deficiency anemia or pernicious anemia (which can be caused by vitamin B₁₂ deficiency); and (3) increased rate of RBC destruction resulting in the *hemolytic* anemias, such as sickle cell anemia (see Chapter 16).

White blood cells defend the body against disease organisms

The **leukocytes**, or **white blood cells (WBCs)**, are specialized to defend the body against harmful bacteria and other microorganisms. Leukocytes are amoeba-like cells capable of independent movement. Some types routinely slip through the walls of blood vessels and enter the tissues. Human blood contains three kinds of granular leukocytes and two types of agranular leukocytes (Table 44-1; see also Fig. 44-4). Both granular and agranular leukocytes are manufactured in the red bone marrow.

Granular leukocytes are characterized by large, lobed nuclei and distinctive granules in their cytoplasm. The three varieties of granular leukocytes are neutrophils, eosinophils, and basophils. **Neutrophils**, the principal phagocytic cells in the blood, are especially adept at seeking out and ingesting bacteria. They also phagocytose dead cells, a cleanup task that is especially demanding after injury or infection. Most granules in neutrophils contain enzymes that digest ingested material.

Eosinophils have large granules that stain bright red with eosin, an acidic dye. Eosinophils increase in number during

allergic reactions and during parasitic (e.g., tapeworm) infestations. The lysosomes of these WBCs contain enzymes such as peroxidases that degrade the cell membranes of parasitic worms and protozoa. These substances can also injure normal tissue. Eosinophils also produce substances that promote an *inflammatory response* (*inflammation*), one of the body's key responses to injury or infection (discussed in Chapter 45).

Basophils exhibit deep blue granules when stained with basic dyes. Like eosinophils, these cells play a role in allergic reactions. Basophils do not contain lysosomes. Granules in their cytoplasm contain **histamine**, a substance that dilates blood vessels and makes capillaries more permeable. Basophils release histamine in injured tissues and in allergic responses. Other basophil granules contain *heparin*, which speeds up fat removal from the blood after you eat a meal high in fat.

Table 44-1 Cell Components of Blood

	Normal Range	Function	Pathology
RED BLOOD CELLS (RBCs)	Male: 4.2–5.4 million/ μ L Female: 3.6–5.0 million/ μ L	Oxygen transport; carbon dioxide transport	Too few: anemia Too many: polycythemia
PLATELETS	150,000–400,000/ μ L	Essential for clotting	Clotting malfunctions; bleeding; easy bruising
WHITE BLOOD CELLS (WBCs)	5000–10,000/ μ L		
Neutrophils	About 60% of WBCs	Phagocytosis	Too many: may be due to bacterial infection, inflammation, myelogenous leukemia
Eosinophils	1%–3% of WBCs	Play role in allergic responses; release proteins that are toxic to parasitic worms; release compounds important in immune responses	Too many: may result from allergic reaction, parasitic infestation
Basophils	1% of WBCs	May play role in prevention of inappropriate clotting; release histamine, which is important in inflammatory responses	
Lymphocytes	25%–35% of WBCs	Produce antibodies; destroy foreign cells	Atypical lymphocytes present in infectious mononucleosis; too many may be due to lymphocytic leukemia, certain viral infections
Monocytes	6% of WBCs	Can differentiate to become macrophages and dendritic cells	May increase in monocytic leukemia and fungal infections

Heparin is an anticoagulant that may help prevent blood from clotting inappropriately within the blood vessels.

Agranular leukocytes lack large, distinctive granules, and their nuclei are rounded or kidney-shaped. Two types of agranular leukocytes are lymphocytes and monocytes. Some **lymphocytes** are specialized to produce antibodies, whereas others directly attack foreign invaders, such as bacteria or viruses (discussed in Chapter 45).

Monocytes are the largest WBCs, reaching 20 μ m in diameter. During infection, monocytes migrate from the blood into the tissues. They phagocytose cells and remove toxic molecules. Monocytes can also differentiate into macrophages or dendritic cells. **Macrophages** are giant scavenger cells that voraciously engulf bacteria, dead cells, and debris. **Dendritic cells** are also important cells of the immune system. For example, some dendritic cells produce compounds that help the body fight viral infection. We discuss macrophages and dendritic cells further in Chapter 45.

Human blood normally has about 7000 WBCs per μ L of blood (only 1 for every 700 RBCs). During bacterial infections, the number may rise sharply, so a WBC count is useful in diagnosis. The proportion of each kind of WBC is determined by a differential WBC count. Table 44-1 shows a normal distribution of WBCs.

Leukemia is a form of blood cancer in which any one of the various kinds of WBCs multiplies rapidly within the bone marrow. Many of these cells do not mature, and their large numbers crowd out developing RBCs and platelets, leading to anemia and impaired clotting. A common cause of death from leukemia is internal hemorrhaging, especially in the brain. Another frequent cause of death is infection; although the WBC count may rise dramatically, the cells are immature and abnormal, and they cannot defend the body against disease organisms.

Thanks to new treatments, survival rates for individuals with leukemia and other blood cancers have recently increased sharply, particularly for children. For example, the survival rate for children younger than five years old with acute lymphocytic leukemia is now higher than 90%.

Platelets function in blood clotting

In most vertebrates other than mammals, the blood contains small, oval, nucleated cells called **thrombocytes** that function in blood clotting. Mammals have **platelets**, tiny spherical or disc-shaped bits of cytoplasm that lack nuclei. About 300,000 platelets per μ L are present in human blood. Platelets are pinched off from very large cells in the bone marrow. Thus, a platelet is not a whole cell but rather is a fragment of cytoplasm enclosed by a membrane.

Platelets function in blood clotting and may also stimulate the immune system. When a blood vessel is cut, it constricts to reduce blood loss. Platelets physically patch the break by sticking to the rough, cut edges of the vessel. As platelets begin to gather, they release substances that attract other platelets. The platelets become sticky and adhere to collagen fibers in the blood vessel wall. Within about 5 minutes after injury, they form a platelet plug, or temporary clot.

At the same time that the temporary clot forms, a stronger, more permanent clot begins to develop. More than 30 chemical substances interact in this complex process. The series of reactions that leads to clotting is triggered when one of the clotting factors in the blood is activated by contact with the injured tissue. In **hemophilia** one of the clotting factors is absent as a result of an inherited genetic mutation (see Chapter 16).

Prothrombin, a plasma protein manufactured in the liver, requires vitamin K for its production. In the presence of clotting

Figure 44-5 Blood clotting

factors, calcium ions, and compounds released from platelets, prothrombin is converted to *thrombin*. Then thrombin catalyzes the conversion of the soluble plasma protein *fibrinogen* to an insoluble protein, **fibrin**. Once formed, fibrin polymerizes, producing long threads that stick to the damaged surface of the blood vessel and form the webbing of the clot. These threads trap blood cells and platelets, which help strengthen the clot. The clotting process is summarized in **FIGURE 44-5**.

CHECKPOINT 44.2

- What are the functions of albumins and globulins?
- Contrast the functions of red blood cells and neutrophils.
- **PREDICT** What would happen if there were a shortage of fibrinogen in the blood?

44.3 Vertebrate Blood Vessels

LEARNING OBJECTIVE

- 4** Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

The vertebrate circulatory system includes three main types of blood vessels: arteries, capillaries, and veins (**FIG. 44-6**). An **artery** carries blood away from a heart chamber toward other tissues. When an artery enters an organ, it divides into many smaller branches called **arterioles**. The arterioles deliver blood into the microscopic **capillaries**. After blood circulates through capillary networks within tissues, capillaries merge to form **veins** that carry the blood back toward the heart.

The wall of an artery or vein has three layers (see Fig. 44-6b). The innermost layer, which lines the blood vessel, consists mainly of **endothelium**, a tissue that resembles squamous epithelium (see Chapter 39). The middle layer is made up of connective tissue and smooth muscle cells, and the outer coat consists of connective tissue rich in elastic and collagen fibers.

Gases and nutrients cannot pass through the thick walls of arteries and veins. Materials are exchanged between the blood and interstitial fluid bathing the cells through the capillary walls, which are only one cell thick. Capillary networks in the body are so extensive that at least one of these tiny vessels is located close to every cell in the body. The total length of all capillaries in the body has been estimated to be more than 96,000 km!

Smooth muscle in the arteriole wall can constrict, a process called **vasoconstriction** or relax, a process called **vasodilation**. Vasoconstriction and vasodilation change the internal diameter of the arteriole. Such changes help maintain appropriate blood pressure and help control the volume of blood passing to

Key Point

The structure of the wall of each type of blood vessel is adapted for the particular function of the vessel; for example, materials are exchanged through the thin walls of capillaries.

(a) The heart pumps blood into arteries. Blood then flows through arterioles, capillaries, and veins, which return it to the heart. Some plasma leaves the capillaries and becomes interstitial fluid. Lymphatic vessels return excess interstitial fluid to the blood through ducts that lead into large veins in the shoulder region. Blood vessels with oxygen-rich blood are shown in red. Those with oxygen-poor blood are shown in blue.

(b) Comparison of the walls of an artery, vein, and capillary. All three vessels are lined with endothelium. The capillary wall is only one cell thick, allowing exchange of materials.

(c) LM of red blood cells passing through capillaries almost in single file.

Figure 44-6 Blood and lymphatic vessels

CONNECT Note that lymph capillaries have dead ends. In what way is the structure of these capillaries connected with their function?

(a) Sphincters closed. When a tissue is inactive, only its metarterioles are open.

(b) Sphincters open. When the tissue becomes active, decreased oxygen tension in the tissue relaxes the precapillary sphincters, and the capillaries open. This process increases the blood supply and thus the delivery of nutrients and oxygen to the active tissue.

Figure 44-7 Blood flow through a capillary network

As a tissue becomes active, the pattern of blood flow through its capillary networks changes.

a particular tissue. Changes in blood flow are regulated by the nervous system in response to the metabolic needs of the tissue as well as by the demands of the body as a whole. For example, when a tissue is metabolizing rapidly, it needs more nutrients and oxygen. During exercise, arterioles within skeletal muscles dilate, increasing blood flow by more than tenfold.

If all your blood vessels dilated at the same time, you would not have enough blood to fill them completely. Normally, your liver, kidneys, and brain receive most of the blood. However, if an emergency suddenly occurred requiring rapid action, your blood would be rerouted quickly in favor of the heart and muscles. At such a time, the digestive system and kidneys can do with less blood because they are not crucial in responding to the crisis.

The small vessels that directly link arterioles with venules (small veins) are **metarterioles**. The true capillaries branch off from the metarterioles and then rejoin them (**FIG. 44-7**). True capillaries also interconnect with one another. Wherever a capillary branches from a metarteriole, a smooth muscle cell serves as a *precapillary sphincter* that opens and closes continuously, directing blood first to one and then to another section of tissue. These precapillary sphincters (along with the smooth muscle in the walls of arteries and arterioles) regulate the blood supply to each organ and its subdivisions.

CHECKPOINT 44.3

- Compare the functions of arteries, capillaries, and veins.
- **PREDICT** Imagine that the smooth muscle in the walls of an individual's arterioles could no longer constrict. What effect would that have on homeostasis?

44.4 Evolution of the Vertebrate Circulatory System

LEARNING OBJECTIVE

- 5** Trace the evolution of the vertebrate circulatory system from fish to mammal.

The vertebrate circulatory system became modified in the course of evolution as the site of gas exchange shifted from gills to lungs and as certain vertebrates became active, endothermic animals with higher metabolic rates. The vertebrate heart has one or two **atria** (sing., *atrium*), chambers that receive blood returning from the tissues, and one or two **ventricles** that pump blood into the arteries (**FIG. 44-8**). Vertebrates in some groups have additional chambers.

The fish heart has one atrium and one ventricle. The atrium pumps blood into the ventricle, which pumps blood into a single circuit of blood vessels. Blood is oxygenated as it passes through capillaries in the gills. After blood circulates through the gill capillaries, its pressure is low, so blood passes very slowly to the other organs. The fish's swimming movements facilitate circulation. Blood returning to the heart has a low oxygen content. A thin-walled *sinus venosus* receives blood returning from the tissues and pumps it into the atrium.

In amphibians blood flows through a double circuit: the **pulmonary circulation** and the **systemic circulation**. Oxygen-rich blood and oxygen-poor blood are kept somewhat separate. The amphibian heart has two atria and one ventricle. A sinus venosus collects oxygen-poor blood returning

Key Point

The four-chambered heart and double circuit that separate oxygen-rich from oxygen-poor blood are important adaptations that evolved as vertebrates diversified and some became active, terrestrial, endothermic animals.

(a) **Fishes.** The single atrium and ventricle of the fish heart are part of a single circuit of blood flow.

(b) **Amphibians.** In amphibians, the heart consists of two atria and one ventricle; blood flows through a double circuit, but oxygen-rich blood mixes with oxygen-poor blood.

(c) **Reptiles (except birds).** The reptilian heart has two atria and two ventricles. In most non-avian reptiles, the wall separating the ventricles is incomplete, so blood from the right and left chambers mixes to some extent. In crocodiles and alligators, the septum is complete, and the heart consists of four separate chambers.

(d) **Birds and mammals.** These animals have two atria and two ventricles. The interventricular septum is complete; oxygen-rich blood is separated from oxygen-poor blood.

Figure 44-8 Evolution of the vertebrate circulatory system

CONNECT How does the separation of oxygen-rich blood and oxygen-poor blood in birds and mammals affect endothermy?

from the veins and pumps it into the right atrium. Blood returning from the lungs passes directly into the left atrium.

Both atria pump into the single ventricle, but oxygen-poor blood is pumped out of the ventricle before oxygen-rich blood enters it. Blood passes into an artery, the *conus arteriosus*, equipped with a fold that helps keep the blood separate. Much of the oxygen-poor blood is directed into the pulmonary circulation, which delivers it to the lungs and skin,

where it is recharged with oxygen. The systemic circulation delivers oxygen-rich blood into arteries that conduct it to the various tissues of the body.

Most non-avian reptiles also have a double circuit of blood flow, made more efficient by a wall that partly divides the ventricles. (In this discussion, birds are considered separately from other reptiles.) Mixing of oxygen-rich and oxygen-poor blood is minimized by the timing of contractions of the left

and right sides of the heart and by pressure differences. In crocodilians (crocodiles and alligators), the wall between the ventricles is complete, so the heart consists of two separate atria and two separate ventricles. Thus, a four-chambered heart first evolved among the non-avian reptiles. In contrast to birds and mammals, amphibians and non-avian reptiles do not ventilate their lungs continuously. Therefore, it would be inefficient to pump blood through the pulmonary circulation continuously. The shunts between the two sides of the heart allow blood to be distributed to the lungs as needed.

In all birds and mammals (and in crocodilians), the *septum* (wall) between the ventricles is complete. Biologists hypothesize that the completely divided heart evolved twice during the course of vertebrate evolution, first in the crocodilian–bird clade and then independently in mammals. The septum between the ventricles prevents oxygen-rich blood in the left chamber from mixing with oxygen-poor blood in the right chamber. The conus arteriosus has split and become the base of the **aorta** (the largest artery) and of the pulmonary artery. No sinus venosus is present as a separate chamber, but a vestige remains as the *sinoatrial node* (the pacemaker).

Complete separation of the right and left sides of the heart requires blood to pass through the heart twice each time it tours the body. The complete double circuit allows birds and mammals to maintain relatively high blood pressures in the systemic circulation and modest pressures in the pulmonary circulation. The higher pressure is necessary for efficient circulation of blood through the body. However, the delicate air sacs and capillaries of the lungs would be damaged by this pressure.

The double circulatory circuit delivers materials to the tissues rapidly and efficiently. Because their blood contains more oxygen per unit volume and circulates more rapidly than in other vertebrates, the tissues of birds and mammals receive more oxygen. As a result, these animals can maintain a higher metabolic rate than other animals and a constant high body temperature even in cold surroundings.

The pattern of blood circulation in birds and mammals can be summarized as follows :

veins (conduct blood from organs) → right atrium → right ventricle → pulmonary arteries → capillaries in the lungs → pulmonary veins → left atrium → left ventricle → aorta → arteries (conduct blood to organs) → arterioles → capillaries → veins

CHECKPOINT 44.4

- What are some of the major adaptations that occurred during the evolution of the vertebrate circulatory system?

44.5 The Human Heart

LEARNING OBJECTIVES

- 6 Describe how the structure and function of the human heart are inter-related; include the heart's conduction system in your answer.
- 7 Trace the events of the cardiac cycle and relate normal heart sounds to these events.
- 8 Define *cardiac output*, describe how it is regulated, and identify factors that affect it.

Not much bigger than a fist and weighing less than a pound, the human heart is a remarkable organ. It beats about 2.5 billion times during an average lifetime, pumping about 300 million L (80 million gal) of blood. To meet the body's changing needs, the heart can vary its output from 5 L to more than 20 L of blood per minute.

Your heart is a hollow, muscular organ located in the chest cavity directly under the breastbone. Its wall consists mainly of cardiac muscle attached to a framework of collagen fibers. The *pericardium*, a tough connective tissue sac, encloses the heart. A smooth layer of endothelium covers the inner surface of the pericardium and the outer surface of the heart. Between these two surfaces is a small *pericardial cavity* filled with fluid, which reduces friction to a minimum as the heart beats.

A wall, or **septum**, separates the right atrium and ventricle from the left atrium and ventricle. Between the atria, the wall is known as the *interatrial septum*; between the ventricles, it is known as the *interventricular septum*. A shallow depression, the *fossa ovalis*, on the interatrial septum marks the place where an opening, the *foramen ovale*, was located in the fetal heart. In the fetus, the foramen ovale lets the blood flow directly from the right to the left atrium, so very little passes to the nonfunctional lungs. A small muscular pouch, called an *auricle*, lies at the upper surface of each atrium.

The heart has valves that close automatically, preventing blood from flowing backward (FIG. 44-9). The valve between the right atrium and right ventricle is called the **right atrioventricular (AV) valve**, or **tricuspid valve**. The *left atrioventricular valve* (between the left atrium and left ventricle) is the **mitral valve**, or *bicuspid valve*. The AV valves are held in place by stout cords, or “heart-strings,” the *chordae tendineae*. These cords attach the valves to the papillary muscles that project from the walls of the ventricles.

When blood returning from the tissues fills the atria, blood pressure on the AV valves forces them to open into the ventricles, filling the ventricles with blood. As the ventricles contract, blood is forced back against the AV valves, pushing them closed. Contraction of the papillary muscles and tensing of the chordae tendineae prevent the valves from opening backward into the atria. These valves are like swinging doors that open in only one direction.

Semilunar valves (named for their flaps, which are shaped like half-moons) guard the exits from the heart. The semilunar valve between the left ventricle and the aorta is the *aortic valve*, and the one between the right ventricle and the pulmonary artery is the *pulmonary valve*. When blood passes out of the

Figure 44-9 Section through the human heart showing the valves

Note the right and left atria, which receive blood, and the right and left ventricles, which pump blood into the arteries. Arrows indicate the direction of blood flow.

ventricles, the flaps of the semilunar valves are pushed aside and offer no resistance to blood flow. When the ventricles are relaxing and filling with blood from the atria, however, blood pressure in the arteries is higher than in the ventricles. Blood then fills the pouches of the valves, stretching them across the artery so that blood cannot flow back into the ventricle.

Each heartbeat is initiated by a pacemaker

Horror films sometimes feature a scene in which a heart cut out of a human body continues to beat. Scriptwriters of these tales actually have some factual basis for their gruesome fantasies because a heart carefully removed from the body can continue to beat for many hours if kept in a nutritive, oxygenated fluid. This is possible because the contractions of cardiac muscle begin within the muscle itself and can occur independently of any nerve supply (**FIG. 44-10a**).

At their ends cardiac muscle fibers (cells) are joined by dense bands called **intercalated discs** (in-ter'-kuh-lay'-ted) (**FIGS. 44-10b** and **c**). These complex junctions contain **gap junctions**. Recall from Chapter 5 that in a gap junction, two cells connect through pores. Gap junctions are of great

physiological importance because they offer very little resistance to the passage of an action potential. Ions move easily through the gap junctions, allowing the entire atrial (or ventricular) muscle mass to contract as one giant cell.

Compared with skeletal muscle that has action potentials typically lasting 1 to 2 milliseconds (msec), the action potentials of cardiac muscle are much longer, several hundred msec. Voltage-activated Ca^{2+} channels open during depolarization of cardiac muscle fibers. Entry of Ca^{2+} contributes to the longer depolarization time. Another factor is a type of K^+ channel that stays open when the cell is at its resting potential but closes during depolarization, lengthening depolarization time by decreasing the permeability of the membrane to K^+ . From experiments on isolated cardiac muscle fibers, investigators determined that spontaneous contraction results from the combination of a slow decrease in K^+ permeability and a slow increase in Na^+ and Ca^{2+} permeability.

A specialized conduction system ensures that the heart beats in a regular and effective rhythm. Each beat is initiated by the **pacemaker**, a small mass of specialized cardiac muscle fibers in the **sinoatrial (SA) node**. The SA node is located in the posterior wall of the right atrium near the opening of a large vein, the superior vena cava. The action potential in the

(a) The sinoatrial (SA) node initiates each heartbeat. The action potential spreads through the muscle fibers of the atria, producing atrial contraction. Transmission is briefly delayed at the atrioventricular (AV) node before the action potential spreads through specialized muscle fibers into the ventricles.

(b) LM of cardiac muscle. 25 μm

(c) TEM of cardiac muscle. 1 μm

Figure 44-10 Conduction system of the heart

When action potentials are initiated by the pacemaker cells in the SA node, gap junctions within the intercalated discs allow the impulses to spread easily from one cardiac muscle fiber to the next within the atria (and within the ventricles). The atria (and then the ventricles) contract as a functional unit.

SA node is triggered mainly by the opening of Ca^{2+} channels. Ends of the SA node fibers fuse with ordinary atrial muscle fibers, so each action potential spreads through the cardiac muscle fibers of both atria, producing atrial contraction.

One group of atrial muscle fibers conducts the action potential directly to the **atrioventricular (AV) node**, located in the right atrium along the lower part of the septum. Here transmission is delayed briefly so that the atria finish contracting before the ventricles begin to contract. From the AV node, the action potential spreads into specialized muscle fibers that make up the **AV bundle**. The AV bundle divides, sending branches into each ventricle. Fibers of the bundle branches divide further, eventually forming small **Purkinje fibers**. These fibers conduct impulses to the muscle fibers of both ventricles.

In summary,

SA node → atrial muscle fibers (atria contract) → AV node → AV bundle → right and left bundle branches → Purkinje fibers → conduct impulses to muscle fibers of both ventricles → ventricles contract

As each wave of contraction spreads through the heart, electric currents flow into the tissues surrounding the heart and onto the body surface. By placing electrodes on the body surface on opposite sides of the heart, a physician can amplify and record the electrical activity. The graph produced is called an **electrocardiogram (EKG or ECG)**. Abnormalities in the EKG indicate disorders in the heart or its rhythm. For example, in **heart block**, impulse transmission is delayed or blocked at some point in the conduction system. Artificial pacemakers can help patients with severe heart block. The pacemaker is implanted beneath the skin, and its electrodes are connected to the heart. This device provides continuous rhythmic impulses that avoid the block and drive the heartbeat.

The cardiac cycle consists of alternating periods of contraction and relaxation

Each minute the heart beats about 70 times. One complete heart-beat takes about 0.8 second and is referred to as a **cardiac cycle**. That portion of the cycle in which contraction occurs is known as **systole**; the period of relaxation is **diastole**. **FIGURE 44-11** shows the sequence of events that occur during one cardiac cycle.

When you listen to the heartbeat with a stethoscope, you can hear two main heart sounds, “lub-dup,” which repeat rhythmically. These sounds result from the heart valves closing. When the valves close, they cause turbulence in blood flow that sets up vibrations in the walls of the heart chambers. The first heart sound, “lub,” is low pitched, not very loud, and fairly long lasting. It is caused mainly by the closing of the AV (mitral and tricuspid) valves and marks the beginning of ventricular systole. The “lub” sound is quickly followed by the higher-pitched, louder, sharper, and shorter “dup” sound. Heard almost as a quick snap, the “dup” marks the closing of the semilunar valves and the beginning of ventricular diastole.

The quality of these sounds tells a discerning physician much about the state of the valves. For example, when a valve

Key Point

The rhythmic changes in electrical activity of the heart are responsible for the cardiac cycle, the pattern of contraction and relaxation that takes place during each heartbeat.

Figure 44-11 The cardiac cycle

The cycle comprises contraction of both atria followed by both ventricles. *White arrows* indicate the direction of blood flow; *dotted lines* indicate the change in size as contraction occurs.

PREDICT How is the cardiac cycle affected when the SA node increases its rate of firing?

does not close tightly, blood may flow backward. When the semilunar valves are injured, a soft, hissing noise (“lub-shhh”) known as a *heart murmur* is heard in place of the normal sound. Valve deformities are sometimes present at birth, or they may result from certain diseases, such as rheumatic fever or syphilis. Diseased or deformed valves can be surgically repaired or replaced with artificial valves.

You can measure your heart rate by placing a finger over the radial artery in your wrist or the carotid artery in your neck and counting the pulsations for 1 minute. **Arterial pulse** is the alternate expansion and recoil of an artery. Each time the left ventricle pumps blood into the aorta, the elastic wall of

the aorta expands to accommodate the blood. This expansion moves in a wave down the aorta and the arteries that branch from it. When the pressure wave passes, the elastic arterial wall snaps back to its normal size.

The nervous system regulates heart rate

Although the heart can beat independently, its rate is, in fact, carefully regulated by the nervous and endocrine systems (FIG. 44-12). Sensory receptors in the walls of certain blood vessels and heart chambers are sensitive to changes in blood pressure. When stimulated, the receptors send messages

Figure 44-12 Some factors that influence cardiac output

to *cardiac centers* in the medulla of the brain. These cardiac centers govern two sets of autonomic nerves that pass to the SA node: parasympathetic nerves and sympathetic nerves. Parasympathetic and sympathetic nerves have opposite effects on heart rate (see Fig. 42-17).

Parasympathetic nerves release the neurotransmitter *acetylcholine*, which slows the heart. Acetylcholine slows the rate of depolarization by increasing the membrane's permeability to K^+ (FIG. 44-13a). Sympathetic nerves release *norepinephrine*, which speeds the heart rate and increases the strength of contraction. Norepinephrine stimulates Ca^{2+} channel opening during depolarization (FIG. 44-13b). Both norepinephrine and acetylcholine act indirectly on ion channels. They activate a *signal transduction* process involving a G protein (see Chapter 6).

Norepinephrine binds to *beta-adrenergic receptors*, one of the two main types of adrenergic receptors. These receptors are targeted by *beta blockers*, drugs that block the actions of norepinephrine on the heart. Beta blockers are used clinically in treating hypertension (high blood pressure) and other types of heart disease.

In response to physical and emotional stressors, the adrenal glands release epinephrine and norepinephrine, which speed the heart. An elevated body temperature also increases heart rate. During fever, the heart may beat more than 100 times per minute. When body temperature is lowered, heart rate decreases.

Stroke volume depends on venous return

The volume of blood one ventricle pumps during one beat is the **stroke volume**. Stroke volume depends mainly on **venous return**, the amount of blood the veins deliver to the heart.

According to *Starling's law of the heart*, if the veins deliver more blood to the heart, the heart pumps more blood into the arteries (within physiological limits). Increased venous return stretches the cardiac muscle fibers more, and they contract with greater force, increasing stroke volume. Norepinephrine released by sympathetic nerves and both norepinephrine and epinephrine released by the adrenal glands during stress also increase the force of contraction of cardiac muscle fibers.

Cardiac output varies with the body's need

The **cardiac output (CO)** is the volume of blood pumped by the left ventricle into the aorta in 1 minute. We can compute the CO by multiplying the stroke volume by the number of times the left ventricle beats per minute. For example, in a resting adult, the heart may beat about 72 times per minute and pump about 70 mL of blood with each contraction.

$$\begin{aligned} \text{CO} &= \text{stroke volume} \times \text{heart rate (number of ventricular contractions per minute)} \\ &= 70 \text{ mL / stroke} \times 72 \text{ strokes / min} \\ &= 5040 \text{ mL / min (about 5 L / min)} \end{aligned}$$

Cardiac output varies with changes in either stroke volume or heart rate (see Fig. 44-12). When stroke volume increases, CO increases. The CO varies dramatically with the changing needs of the body. During stress or heavy exercise, the normal heart can increase its CO fivefold so that it pumps 20 to 30 L of blood per minute.

CHECKPOINT 44.5

- List the sequence of events that occurs during cardiac conduction.
- PREDICT** A patient's mitral valve (left AV valve) does not close completely at the beginning of ventricular systole. What effect would this have on the cardiac cycle?
- Imagine that you are feeling very anxious as you walk to the podium to deliver a speech. If your heart rate increases to 100 beats per minute and your stroke volume is 100 mL per stroke, what is your cardiac output?

44.6 Blood Pressure

LEARNING OBJECTIVE

- Identify factors that determine and regulate blood pressure and compare blood pressure in different types of blood vessels.

Blood pressure is the force exerted by the blood against the inner walls of the blood vessels. It is determined by CO (cardiac output), blood volume, and resistance to blood flow

- 1 Parasympathetic neuron releases acetylcholine.
- 2 Acetylcholine binds with receptors on plasma membrane of cardiac muscle.
- 3 Receptor activates G protein.
- 4 G protein binds with K^+ channel, opening it.
- 5 K^+ leaves the cell, hyperpolarizing the membrane. Action potentials occur more slowly. Heart rate decreases.

(a) Parasympathetic action on cardiac muscle.

- 1 Sympathetic neuron releases norepinephrine.
- 2 Norepinephrine binds with receptors on the plasma membrane of cardiac muscle.
- 3 Receptor activates G protein.
- 4 G protein activates adenylyl cyclase, which converts ATP to cyclic AMP (cAMP).
- 5 Cyclic AMP activates protein kinase.
- 6 Protein kinase phosphorylates Ca^{2+} channels so that they open more easily when neuron is depolarized. Action potentials occur more rapidly. Heart rate increases.

(b) Sympathetic action on cardiac muscle.

Figure 44-13 Actions of parasympathetic and sympathetic neurons on cardiac muscle

Parasympathetic neurons release acetylcholine, which slows the heart rate. Sympathetic neurons release norepinephrine, which increases both the heart rate and the strength of contraction. Each of these neurotransmitters works through a G protein and initiates a signal transduction process.

(FIG. 44-14a). When CO increases, the increased blood flow causes a rise in blood pressure. When CO decreases, the decreased blood flow causes a fall in blood pressure. If the volume of blood is reduced by hemorrhage or chronic bleeding, the blood pressure drops. In contrast, an increase in blood volume results in an increase in blood pressure. For example, a

high dietary intake of salt causes water retention, which increases blood volume and raises blood pressure.

Blood flow is impeded by resistance. When the resistance to flow increases, blood pressure rises. *Peripheral resistance* is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall. In the blood of a healthy person, viscosity remains fairly constant and is only a minor influence on changes in blood pressure. More important is the friction between blood and the blood vessel wall. The length and diameter of a blood vessel determine the amount of surface area in contact with the blood. Blood vessel length does not change, but the diameter, especially of an arteriole, does. A small change in blood vessel diameter causes a big change in blood pressure. Constriction of blood vessels raises blood pressure; dilation lowers blood pressure.

Blood pressure in arteries rises during systole and falls during diastole. The National Institutes of Health defines *normal blood pressure* as a systolic pressure of less than 120 and a diastolic pressure of less than 80. An example of a normal blood pressure, measured in the upper arm with a sphygmomanometer, is 110/73 mm of mercury, abbreviated mm Hg. Systolic pressure is indicated by the first number, diastolic by the second.

If you have a blood pressure of 120 to 139 systolic over 80 to 89 diastolic, you are considered *prehypertensive*, and you need to modify your lifestyle to prevent cardiovascular disease and stroke. Lifestyle changes that will reduce your risk include exercising, losing excess weight, following a heart-healthy diet, reducing salt intake, limiting alcohol, and not smoking.

If your systolic pressure consistently measures 140 mm Hg or higher or your diastolic pressure measures 90 mm Hg or higher, you have **hypertension**, or high blood pressure. Hypertension is a

risk factor for atherosclerosis and other cardiovascular disease (discussed later in this chapter).

In hypertension there is usually increased vascular resistance, especially in the arterioles and small arteries. The heart's workload increases because it must pump against this greater resistance. If this condition persists, the left ventricle

(a) Blood pressure depends on blood flow and resistance to that flow. A variety of factors affect blood flow and resistance.

Figure 44-14 Blood pressure

Area in graph refers to the surface area of blood vessels in contact with blood.

enlarges and may deteriorate in function. Heredity, aging, race, and ethnicity can increase the risk of hypertension. Modifiable risk factors include being overweight, eating too much sodium, smoking, and drinking too much alcohol.

Blood pressure varies in different blood vessels

As you might predict, blood pressure is greatest in the large arteries and decreases as blood flows away from the heart and through the smaller arteries and capillaries (FIG. 44-14b). By the time blood enters the veins, its pressure is very low, even approaching zero. Flow rate can be maintained in veins at low pressure because they are low-resistance vessels. Their diameter is larger than that of corresponding arteries, and their walls have little smooth muscle. Flow of blood through veins depends on several factors, including skeletal muscle movement, which compresses veins. Most veins larger than 2 mm (0.08 in.) in diameter that conduct blood against the force of gravity are equipped with *valves* that prevent back-flow. Such valves usually consist of two cusps formed by inward extensions of the vein wall (FIG. 44-15).

When a person stands perfectly still for a long time, as when a soldier stands at attention or a store clerk stands at a cash register, blood tends to pool in the veins. When fully distended, veins can accept no more blood from the capillaries. Pressure increases in the capillaries, and large amounts of plasma are forced out of the circulation through the thin capillary walls. Within just a few minutes, as much as 20% of the blood volume can be lost from the circulation, with drastic effect. Arterial blood pressure falls dramatically, reducing blood flow to the brain.

Figure 44-15 Venous blood flow

Contraction of skeletal muscles helps move blood through the veins.

(b) Blood pressure varies in different types of blood vessels. Systolic and diastolic variations in arterial blood pressures are shown. Note that the venous pressure drops below zero (below atmospheric pressure) near the heart.

Sometimes the resulting lack of oxygen in the brain causes the person to faint. Fainting is a protective response because lying in a prone position increases blood supply to the brain. In fact, lifting a person who has fainted to an upright position can result in circulatory shock and even death.

Blood pressure is carefully regulated

Each time you get up from a horizontal position, your blood pressure changes. Several mechanisms interact to maintain normal

blood pressure so that you do not faint when you get out of bed each morning or change position during the day. When blood pressure decreases, sympathetic nerves to the blood vessels stimulate vasoconstriction, causing the pressure to rise again.

Baroreceptors, specialized receptors in the walls of certain arteries and in the heart wall, are sensitive to changes in blood pressure. When an increase in blood pressure stretches the baroreceptors, messages are sent to the cardiac and vasomotor centers in the medulla of the brain. The cardiac center stimulates parasympathetic nerves that slow the heart, lowering blood pressure. The vasomotor center inhibits sympathetic nerves that constrict arterioles; this action causes vasodilation, which also lowers blood pressure. These neural reflexes continuously work in a complementary way to maintain blood pressure within normal limits.

Several hormones are also involved in regulating blood pressure (discussed in more detail in Chapters 48 and 49). In response to low blood pressure, the kidneys release **renin**, which activates the *renin-angiotensin-aldosterone pathway*. Renin acts on a plasma protein (angiotensinogen), triggering a cascade of reactions that produces the hormone **angiotensin II**, a powerful vasoconstrictor. Vasoconstriction *increases* blood pressure, restoring homeostasis. Angiotensin II also acts indirectly to maintain blood pressure by increasing the synthesis and release of the hormone **aldosterone** by the adrenal glands. Aldosterone increases retention of Na^+ by the kidneys, resulting in greater fluid retention and increased blood volume.

When the body becomes dehydrated, the osmotic concentration of the blood increases. In response, the posterior lobe of the pituitary gland releases **antidiuretic hormone (ADH)**. This hormone increases reabsorption of water in the kidneys (and only a small volume of concentrated urine is produced). Blood volume increases, raising blood pressure and restoring homeostasis.

When blood volume increases, the atria of the heart release a hormone called **atrial natriuretic peptide (ANP)**. This hormone increases sodium excretion. As a result, a large volume of dilute urine is produced, and blood pressure *decreases*. Nitric oxide also helps regulate blood pressure by causing vasodilation, thus decreasing blood pressure.

CHECKPOINT 44.6

- How does constriction of arterioles affect blood pressure?
- How does blood pressure in arteries compare with blood pressure in veins?

44.7 The Pattern of Circulation

LEARNING OBJECTIVE

- 10** Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.

Most vertebrates other than fishes have a double circuit of blood vessels: (1) the **pulmonary circulation** connects the

The right side of the heart receives oxygen-poor blood returning from the tissues and pumps it into the pulmonary circulation. The left side of the heart receives oxygen-rich blood from the lungs and pumps it into the systemic circulation.

Figure 44-16 Systemic and pulmonary circulation

In this highly simplified diagram, *red* represents oxygen-rich blood, and *blue* represents oxygen-poor blood. The *light blue screens* highlight systemic circulation, and the *light pink screens* highlight pulmonary circulation.

CONNECT Although not evident in the view depicted in the illustration, the chambers of the left and right ventricles are the same size and pump equal volumes of blood. However, the muscle of the left ventricle is much thicker than that of the right ventricle. How does this difference relate to their functions?

heart and lungs; and (2) the **systemic circulation** connects the heart with all the body tissues. You can trace this general pattern of circulation in **FIGURE 44-16**.

The pulmonary circulation oxygenates the blood

Blood from the tissues returns to the right atrium of the heart. This oxygen-poor blood, loaded with carbon dioxide, is pumped by the right ventricle into the pulmonary circulation. As it emerges from the heart, the large pulmonary trunk branches to form the *pulmonary arteries* that deliver blood to the lungs. *The pulmonary arteries are the only arteries in the body that carry oxygen-poor blood.*

In the lungs the pulmonary arteries branch into smaller and smaller vessels. These blood vessels give rise to extensive networks of pulmonary capillaries that surround the air sacs of the lungs. As blood circulates through the pulmonary capillaries, carbon dioxide diffuses out of the blood and into the air sacs. Oxygen from the air sacs diffuses into the blood. By the time it enters the *pulmonary veins* leading back to the left atrium of the heart, the blood is recharged with oxygen. *Pulmonary veins are the only veins in the body that carry blood rich in oxygen.* In summary, blood flows through the pulmonary circulation in the following sequence:

right atrium → right ventricle → pulmonary arteries → pulmonary capillaries (in lungs) → pulmonary veins → left atrium

The systemic circulation delivers blood to the tissues

Blood entering the systemic circulation is pumped by the left ventricle into the **aorta**, the largest artery. Arteries that branch off from the aorta conduct blood to all regions of the

body. Some of the principal branches include the *coronary arteries* to the heart wall itself, the *carotid arteries* to the brain, the *subclavian arteries* to the shoulder region, the *mesenteric artery* to the intestine, the *renal arteries* to the kidneys, and the *iliac arteries* to the legs (**FIG. 44-17**). Each of these arteries gives rise to smaller and smaller vessels, somewhat like branches of a tree that divide until they form tiny twigs. Eventually, blood flows into capillary networks within each tissue or organ.

Blood returning from the capillary networks within the brain passes through the *jugular veins*. Blood from the shoulders and arms drains into the *subclavian veins*. These veins and others returning blood from the upper portion of the body merge to form a very large vein that empties blood into the right atrium. In humans this vein is called the **superior vena cava**. The *renal veins* from the kidneys, *common iliac veins* from the lower limbs, *hepatic veins* from the liver, and other veins from the lower portion of the body return blood to the large **inferior vena cava**. This very large vein also delivers blood to the right atrium.

As an example of blood circulation through the systemic circuit, let us trace a drop of blood from the heart to the right leg and back to the heart:

left atrium → left ventricle → aorta → right common iliac artery → smaller arteries in leg → capillaries in leg → small veins in leg → common iliac vein → inferior vena cava → right atrium

Figure 44-17 Blood circulation through some of the principal arteries and veins of the human body

Blood vessels carrying oxygen-rich blood are red; blood vessels carrying oxygen-poor blood are blue.

In most fishes, small amphibians, and in some non-avian reptiles, the heart muscle is spongy and receives oxygen directly from the blood as it passes through the heart chambers. However, in other vertebrates, including birds and mammals, the walls of the heart are too thick for nutrients and oxygen to reach all the muscle fibers by diffusion. Instead, the cardiac muscle has its own system of blood vessels, the **coronary circulation**. In humans, *coronary arteries* give rise to a network of capillaries within the heart wall. The *coronary veins* join to form a large vein, the *coronary sinus*, which empties directly into the right atrium.

Blood almost always travels from artery to capillary to vein to the heart. An exception occurs in the **hepatic portal system**. Instead of leading directly back to the heart (as most veins do), the hepatic portal vein delivers nutrients from the intestine to the liver. Within the liver, the hepatic portal vein gives rise to an extensive network of tiny blood sinuses. As blood courses through the hepatic sinuses, liver cells remove nutrients and store them. Eventually, liver sinuses merge to form hepatic veins, which deliver blood to the inferior vena cava.

CHECKPOINT 44.7

- What sequence of blood vessels and heart chambers would a red blood cell pass through on its way (1) from the carotid artery to the superior vena cava and (2) from the renal vein to the renal artery?
- What is the function of the hepatic portal system? How does its sequence of blood vessels differ from that in most other circulatory routes?

44.8 The Lymphatic System

LEARNING OBJECTIVE

- 11** Describe the inter-relationship between the structures and functions of the lymphatic system.

In addition to the blood circulatory system, vertebrates have an accessory circulatory system, the **lymphatic system** (FIG. 44-18). The lymphatic system (1) collects and returns interstitial fluid to the blood, (2) launches immune responses that defend the body against disease organisms, and (3) absorbs lipids from the digestive tract. In this section we focus on the first function. We discuss immunity in Chapter 45 and lipid absorption in Chapter 47.

The lymphatic system consists of lymphatic vessels and lymph tissue

The lymphatic system consists of (1) an extensive network of *lymphatic vessels*, or simply *lymphatics*, that conduct **lymph**, the clear, watery fluid formed from interstitial fluid; and (2) *lymph tissue*, a type of connective tissue with large numbers of lymphocytes. Lymph tissue is organized into small

Figure 44-18 Human lymphatic system

Note that the lymphatic vessels extend into most tissues of the body, but the lymph nodes are clustered in certain regions. The right lymphatic duct drains lymph from the upper right quadrant of the body and returns fluid to the right subclavian vein. The thoracic duct drains lymph from other regions of the body and returns fluid to the left subclavian vein.

masses of tissue called **lymph nodes** and *lymph nodules*. The tonsils, thymus gland, and spleen, which consist mainly of lymph tissue, are also part of the lymphatic system.

Tiny “dead-end” capillaries of the lymphatic system extend into almost all body tissues (FIG. 44-19). Interstitial fluid enters lymph capillaries, where it becomes lymph. Lymph capillaries join to form larger lymphatics (which you can think of as lymph veins). There are no lymph arteries.

Lymph passes from lymph capillaries into lymphatics, which at certain locations empty into lymph nodes. As lymph

Figure 44-19 Lymph capillaries

Lymph capillaries drain excess interstitial fluid from the tissues. Note that blood capillaries are connected to vessels at both ends, whereas lymph capillaries (shown in green) are “dead-end streets.” The white arrows indicate direction of blood and lymph flow. The black arrows indicate direction of interstitial fluid flow.

moves through the lymph nodes, phagocytes filter out bacteria and other harmful materials. The lymph then flows into lymphatics that conduct it away from the lymph node. Lymphatics from all over the body conduct lymph toward the shoulder region. These vessels join the circulatory system at the base of the subclavian veins by way of ducts: the *thoracic duct* on the left side and the *right lymphatic duct* on the right.

Tonsils are masses of lymph tissue under the lining of the oral cavity and throat. (When enlarged, the pharyngeal tonsils in back of the nose are called *adenoids*.) Tonsils help protect the respiratory system from infection by destroying bacteria and other foreign matter that enter the body through the mouth or nose. Unfortunately, tonsils are sometimes overcome by invading bacteria and become the site of frequent infection themselves.

Some vertebrates, such as frogs, have lymph “hearts,” which pulsate and squeeze lymph along. However, in mammals the walls of lymphatic vessels themselves pulsate. Valves within the lymphatics prevent lymph from flowing backward. When muscles contract or when arteries pulsate, pressure on the lymphatic vessels increases lymph flow. The rate at which lymph flows is slow and variable. The total lymph flow is about 100 mL per hour, which is far slower than the 5 L per minute of blood flowing in the cardiovascular system.

The lymphatic system plays an important role in fluid homeostasis

When blood enters a capillary network, it is under rather high pressure, so some plasma is forced out of the capillaries into the tissues. Once it leaves the blood vessels, this fluid is called *interstitial fluid*, or tissue fluid. It contains no red blood cells

or platelets and only a few white blood cells. Its protein content is about one-fourth that found in plasma because proteins are too large to pass easily through capillary walls. However, smaller molecules dissolved in the plasma do pass out with the fluid leaving the blood vessels. Thus, interstitial fluid contains oxygen, glucose, amino acids and other small nutrients, and a variety of salts. This nourishing fluid bathes all the cells.

Three factors are responsible for *net filtration pressure*, which is the tendency for plasma to leave the blood at the arterial end of a capillary and enter the interstitial fluid (FIG. 44-20). The main force is *hydrostatic pressure*, the blood pressure against the capillary wall. This effect is augmented by the osmotic pressure of the interstitial fluid. The principal opposing force is the osmotic pressure of the blood, which is greater than the osmotic pressure of the interstitial fluid and restrains fluid loss from the capillary.

At the venous ends of the capillaries, the blood hydrostatic pressure is much lower, and the osmotic pressure of the blood draws fluid back into the capillary. However, not as much fluid is absorbed back into the circulation at the venous ends of capillaries as is filtered out at the arterial ends. Furthermore, protein does not return effectively into the venous capillaries and instead tends to accumulate in the interstitial fluid. These potential problems are so serious that without the lymphatic system, fluid balance in the body would be significantly disturbed within a few hours, and death would occur within about 24 hours. The lymphatic system preserves fluid balance by collecting interstitial fluid, including the protein that accumulates in it, and returning it to the circulation.

The walls of the lymph capillaries consist of endothelial cells that overlap slightly. When interstitial fluid accumulates, it presses against these cells, pushing them inward like tiny swinging doors that swing in only one direction. As fluid accumulates within the lymph capillary, these cell doors are pushed closed.

Obstruction of lymphatic vessels causes *lymphedema*, swelling from excessive accumulation of interstitial fluid. Lymphatic vessels can be blocked as a result of injury, inflammation, surgery, or parasitic infection. For example, when a breast is removed (mastectomy) because of cancer, lymph nodes in the armpit are often removed to prevent the spread of cancer cells. The disrupted lymph circulation may cause the patient’s arm to swell. Treatment focuses on minimizing the swelling and controlling discomfort and pain.

CHECKPOINT 44.8

- VISUALIZE** Draw a diagram illustrating the relationships among plasma, interstitial fluid, and lymph.
- How does the lymphatic system help maintain fluid balance?

44.9 Cardiovascular Disease

LEARNING OBJECTIVE

- 12** Trace the progression of atherosclerosis and describe at least five risk factors for cardiovascular disease.

- 1 At the arterial end of a capillary, blood pressure forces plasma out of the capillary. The osmotic pressure of the blood is an opposing force acting to draw fluid into the blood.
- 2 Osmotic pressure of the interstitial fluid contributes to the net filtration pressure but does not change much between arterial and venous ends of the capillary.
- 3 At the venous end of a capillary, fluid enters the blood because blood pressure is much lower.

Figure 44-20 Fluid movement between blood and interstitial fluid

The exchange of dissolved materials between blood and interstitial fluid depends on fluid movement between the blood and the interstitial fluid surrounding the capillary. This fluid movement depends on the hydrostatic pressure of the blood and on osmotic pressures. More fluid leaves at the arterial end of each capillary than is returned at the venous end. The lymphatic system collects the excess interstitial fluid and returns it to the blood. The numbers given are hypothetical and represent millimeters of mercury.

Cardiovascular disease includes heart and blood vessel diseases, including cerebrovascular accidents (strokes). Cardiovascular disease is the leading cause of death for both men and women in the United States and in the world. According to the American Heart Association, cardiovascular disease causes more than 800,000 deaths (about 1 in every 3 deaths) each year in the United States. Cardiovascular disease kills more people than all types of cancer combined! Death typically results from a combination of *atherosclerosis*, *thrombosis* (clotting), and *hypertension* (high blood pressure).

Atherosclerosis develops progressively

Atherosclerosis is a progressive disease in which the walls of certain arteries become damaged and inflamed, and the lumen (opening) becomes narrowed as a result of lipid deposits in their walls. Although it can affect almost any artery, the disease most often develops in the aorta and in the coronary and cerebral arteries. The following sequence of events occurs in the development of atherosclerosis.

1. The earliest events in atherosclerosis begin when excess low-density lipoprotein (LDL) (known as “bad” cholesterol) in the blood enters the inner layer of blood vessels. (LDLs are discussed further in Chapter 47; uptake of LDL by cells is

described in Chapter 5 and illustrated in Figure 5-22.) Recall that the inner layer of a blood vessel is made up of endothelial cells; the inner lining is the endothelium. Excess LDLs in the blood vessel wall become oxidized by **free radicals**, highly reactive, toxic compounds with unpaired electrons. (Free radicals bond with other compounds in cells and interfere with normal function.) Oxidized LDLs accumulate between and beneath the endothelial cells.

2. Endothelial cells respond to the oxidized LDLs by releasing compounds that attract monocytes. These white blood cells enter the tissues and trigger an inflammatory response. Monocytes develop into macrophages, which phagocytize the oxidized LDLs. As they become filled with LDLs, the macrophages appear foamy and are called *foam cells*.
3. Large numbers of foam cells lead to the development of fatty streaks, thought to be the initial lesion in the progression of atherosclerosis. (Interestingly, fatty streaks have been identified in the arteries of some children and adolescents.) Cells at the site of inflammation release compounds that trigger underlying smooth muscle fibers to migrate from the muscle layer of the artery and cover the fatty streaks. The smooth muscle fibers settle just below the endothelium of the artery and multiply there. The deposited lipids together with the smooth muscle fibers form the developing *atherosclerotic plaque*. Inflammation, discussed in

Chapter 45, is one of the body's most important responses to infection or injury. However, inflammation can also have harmful effects and appears to be an important factor in the development of atherosclerosis.

4. Connective tissue fibers also proliferate and produce collagen, which adds to the plaque. Cells of the immune system migrate to the area and produce substances that maintain chronic inflammation in the inner layer of the arterial wall. Later, calcium may also be deposited in the plaque, hardening the wall of the artery and narrowing it.
5. Smooth muscle fibers form a protective *fibrous cap*, which walls off the plaque from the inner lining of the artery and the blood. Macrophages and other cells eventually die within the plaque, recruiting more macrophages to the area to clean up the debris.

The progression of atherosclerosis can continue for decades without causing symptoms. However, as atherosclerotic plaque builds, arteries eventually lose their ability to stretch when filled with blood. Also, as the walls thicken, the diameter of the artery decreases, and it gradually becomes occluded (blocked), as shown in **FIGURE 44-21**.

Atherosclerosis has many effects

Compared with healthy blood vessels, occluded vessels deliver less blood to the tissues. As a result, tissues become *ischemic*, or lacking in blood, which reduces their oxygen and nutrient supply. In *ischemic heart disease*, the increased need for oxygen during exercise or emotional stress results in the pain characteristic of *angina pectoris*. Nitroglycerin, in the form of pills or a patch, dilates veins, decreasing venous return. Cardiac output is lowered, so the heart is not working as hard and requires less oxygen. Nitroglycerin also dilates the coronary arteries slightly, allowing more blood to reach the heart muscle. *Calcium ion channel blockers* are drugs that slow the

heart by inhibiting the passage of Ca^{2+} into cardiac muscle fibers. They also dilate the coronary arteries.

Myocardial infarction (MI), or heart attack, is a very serious, often fatal, consequence of cardiovascular disease. MI is the first symptom of cardiovascular disease for about 65% of men and almost 50% of women affected by atherosclerosis. Myocardial infarction is a leading cause of death and disability in the United States. It often results from a sudden decrease in coronary blood supply. If only a small region of cardiac muscle is affected, the heart may continue to function. Cells in the region deprived of oxygen die and are replaced by scar tissue.

The sudden decrease in blood supply associated with MI often occurs when inflammation causes the fibrous cap over the atherosclerotic plaque to break open. Platelets adhere to the roughened arterial wall and initiate clotting. A *thrombus* is a clot that forms within a blood vessel. A thrombus that migrates to a coronary artery (or develops within a coronary artery) can partially or completely block the flow of blood to part of the heart muscle. When a critical region of cardiac muscle is deprived of its blood supply, the heart may stop beating. This condition, called *cardiac arrest*, can result in death within a few minutes.

An episode of ischemia may trigger a fatal arrhythmia such as *ventricular fibrillation*, a condition in which the ventricles contract very rapidly without actually pumping blood. The pulse may stop, and blood pressure may fall precipitously. Ventricular fibrillation has been linked with 65% to 85% of cardiac arrests. The only effective treatment for fibrillation is *defibrillation* with electric shock. The shock appears to depolarize all the muscle fibers in the heart so that its timing mechanism can reset.

When atherosclerosis develops in the cerebral arteries, less blood is delivered to the brain. This condition can lead to a *cerebrovascular accident (CVA)*, commonly referred to as a *stroke*. Most CVAs are caused by ischemia, typically as a result of throm-

bosis. Others are caused by uncontrolled hypertension, which can cause blood vessels in the brain to leak or rupture.

Cardiovascular disease can be treated

Current treatment for patients with progressive cardiovascular disease includes certain drugs; surgical procedures aimed at restoring and improving blood flow; and importantly, education regarding lifestyle changes that reduce risk factors. Among the many types of medications prescribed for treating cardiovascular disease are statins, medications that lower cholesterol level; aspirin, which reduces the tendency for blood clotting; beta-blockers, drugs that block the effects of epinephrine (adrenaline); and ACE inhibitors (angiotensin-converting enzyme), drugs that decrease blood pressure. By inhibiting ACE, a key

Figure 44-21 Atherosclerosis

LMs of cross sections through two arteries showing changes that take place in atherosclerosis.

enzyme responsible for the synthesis of angiotensin II, these drugs decrease blood pressure. Angiotensin II is a powerful vasoconstrictor. This hormone also promotes production of aldosterone and increases sodium reabsorption in the kidneys, leading to water retention. (Angiotensin II and aldosterone are discussed further in Chapter 48.) Drugs that inhibit inflammation are also used to treat cardiovascular disease.

Surgical procedures to treat cardiovascular disease include angioplasty and stent placement, and coronary bypass surgery. *Angioplasty* involves inserting a small balloon into an occluded coronary artery. Inflating the balloon breaks up the plaque in the arterial wall and thus widens the vessel. A stent (a mesh tube) left in the artery helps keep the artery open.

In *coronary bypass surgery*, veins from another location in the patient's body are grafted around occluded coronary arteries. The newly positioned blood vessels allow blood to flow around the blocked arteries, restoring adequate blood flow to the affected area.

Future treatment for damaged hearts may include stem cell therapies. Researchers have demonstrated that patients treated with stem cells harvested from their own bone marrow (in addition to standard treatment) had better recoveries than patients who did not receive stem cell treatment.

The risk of cardiovascular disease can be lowered

Many studies have shown that a healthy lifestyle lowers the risk for cardiovascular disease. For example, exercise increases the concentration of HDLs, which protect against heart disease. A balanced diet low in sodium, cholesterol, saturated and *trans* fat, and rich in fruits and vegetables is important.

Several major *modifiable* risk factors for cardiovascular disease have been identified:

1. *Elevated LDL-cholesterol levels in the blood.* These levels are associated with diets rich in total calories, total fats, saturated fats, and cholesterol. Genetic predisposition can also be a factor.

2. *Hypertension.* The higher the blood pressure is, the greater the risk of cardiovascular disease. The hormone angiotensin II, which at abnormally high levels is thought to contribute to hypertension, also stimulates inflammation.
3. *Cigarette smoking.* The risk of developing atherosclerosis is three to six times greater in smokers than in nonsmokers and is directly proportional to the number of cigarettes smoked daily. Nicotine constricts blood vessels, and carbon monoxide in the smoke damages the inner lining of blood vessels. Components of cigarette smoke cause oxidants to form, which may contribute to the inflammation by increasing oxidation of the altered LDL in the arterial wall.
4. *Diabetes mellitus.* In this endocrine disorder, glucose is not metabolized normally. The body shifts to fat metabolism, and there is a marked increase in circulating lipids, leading to atherosclerosis. Impaired glucose tolerance is also a risk factor.
5. *Physical inactivity.* Physical inactivity contributes to more than 35% of the more than 600,000 deaths related to heart disease in the United States each year. Exercise reduces the concentrations of triacylglycerols (triglycerides) and cholesterol in the blood. (These lipids have been associated with heart disease.)
6. *Overweight and obesity.* Being overweight can affect cholesterol levels and increase the risk of hypertension and diabetes.

The risk of developing cardiovascular disease also increases with age. Other probable risk factors currently being studied are hereditary predisposition, hormone levels, stress and behavior patterns, and dietary factors.

CHECKPOINT 44.9

- **PREDICT** Over a period of years, Joe pays little attention to his diet. He eats mainly fried foods. He also smokes cigarettes. What outcome would you predict for Joe?
- **CONNECT** How might inflammation contribute to blocked arteries?

Summary: Focus on Learning Objectives

44.1 Types of Circulatory Systems (page 937)

1 Contrast internal transport in animals with no circulatory system, animals with an open circulatory system, and animals with a closed circulatory system.

- Small, simple invertebrates depend on **diffusion** for internal transport. Larger animals require a specialized **circulatory system**, which typically consists of **blood**, a **heart**, and a system of **blood vessels** or spaces through which blood circulates. In all animals, **interstitial fluid**, the tissue fluid between cells, brings oxygen and nutrients into contact with cells.
- Arthropods and most mollusks have an **open circulatory system** in which blood flows into a **hemocoel**, bathing the tissues directly.
- Some invertebrates and all vertebrates have a **closed circulatory system** in which blood flows through a continuous circuit of blood vessels.
- The vertebrate circulatory system consists of a muscular heart that pumps blood into a system of blood vessels. The circulatory system transports nutrients, oxygen, wastes, and hormones; helps maintain fluid balance, appropriate pH, and body temperature; and defends the body against disease.

44.2 Vertebrate Blood (page 939)

2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets.

- **Plasma** consists of water, salts, substances in transport, and **plasma proteins**, including albumins, globulins, and fibrinogen.
- **Red blood cells (RBCs)**, also called **erythrocytes**, transport oxygen and carbon dioxide. Red blood cells produce large quantities of **hemoglobin**, a red pigment that transports oxygen.
- **White blood cells (WBCs)**, also called **leukocytes**, defend the body against disease organisms. **Lymphocytes** and **monocytes** are agranular white blood cells; **neutrophils**, **eosinophils**, and **basophils** are granular white blood cells. Monocytes can develop into **macrophages** and **dendritic cells**.
- **Platelets** patch damaged blood vessels and release substances essential for blood clotting.

3 Summarize the sequence of events involved in blood clotting.

- Damaged cells and platelets release substances that activate clotting factors. Prothrombin is converted to *thrombin*, which catalyzes the conversion of *fibrinogen* to an insoluble protein, **fibrin**. Fibrin forms long threads that make up the webbing of the clot.

44.3 Vertebrate Blood Vessels (page 942)

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

- **Arteries** carry blood away from a heart chamber. **Arterioles** are small arteries that regulate blood pressure by constricting (**vasoconstriction**) and dilating (**vasodilation**). **Capillaries** are the thin-walled exchange vessels through which blood and tissues transfer materials. **Veins** return blood to a heart chamber.

44.4 Evolution of the Vertebrate Circulatory System (page 944)

5 Trace the evolution of the vertebrate circulatory system from fish to mammal.

- The vertebrate heart has one or two **atria**, which receive blood, and one or two **ventricles**, which pump blood into the arteries. The fish heart consists of a single atrium and ventricle that are part of a single circuit of blood flow.
- In terrestrial vertebrates, circulatory systems separate oxygen-rich blood from oxygen-poor blood, which allows the higher metabolic rate needed to support an active terrestrial lifestyle. Amphibians have two atria and a single ventricle. Blood flows through a double circuit so that oxygen-rich blood is partly separated from oxygen-poor blood. Most non-avian reptiles have a wall that partly divides the ventricles, minimizing the mixing of oxygen-rich and oxygen-poor blood.
- The four-chambered hearts of birds and mammals separate oxygen-rich blood from oxygen-poor blood.

44.5 The Human Heart (page 946)

6 Describe how the structure and function of the human heart are inter-related; include the heart's conduction system in your answer.

- The heart is enclosed by a *pericardium* and has valves that prevent backflow of blood. The valve between the right atrium and ventricle is the **right atrioventricular (AV) valve**, or **tricuspid valve**. The valve between the left atrium and ventricle is the **mitral valve**. **Semilunar valves** guard the exits from the heart. Cardiac muscle fibers are joined by **intercalated discs**.
- The **pacemaker** in the **sinoatrial (SA) node** initiates each heartbeat. A specialized electrical conduction system coordinates heartbeats.

7 Trace the events of the cardiac cycle and relate normal heart sounds to these events.

- One complete heartbeat makes up a **cardiac cycle**. The period of contraction is called **systole**. The period of relaxation is **diastole**. At the beginning of ventricular systole, the closing of the AV valves makes a low-pitched "lub" sound. At the beginning of ventricular diastole, the closing of the semilunar valves makes a short, loud "dup" sound.

8 Define cardiac output, describe how it is regulated, and identify factors that affect it.

- **Cardiac output (CO)** equals **stroke volume** multiplied by heart rate. Stroke volume depends on *venous return* and on neural messages and hormones, especially epinephrine and norepinephrine. According to *Starling's law of the heart*, the more blood delivered to the heart by the veins, the more blood the heart pumps.
- Heart rate is regulated mainly by the nervous system and is influenced by hormones and body temperature.

44.6 Blood Pressure (page 950)

9 Identify factors that determine and regulate blood pressure and compare blood pressure in different types of blood vessels.

- **Blood pressure** is the force blood exerts against the inner walls of the blood vessel. Blood pressure is greatest in the arteries and decreases as blood flows through the capillaries.
- Blood pressure depends on cardiac output, blood volume, and resistance to blood flow. *Peripheral resistance* is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall.

- **Baroreceptors** are sensitive to blood pressure changes. They send messages to the cardiac and vasomotor centers in the medulla of the brain. When informed of an increase in blood pressure, the cardiac center stimulates parasympathetic nerves that slow the heart rate. The vasomotor center inhibits sympathetic nerves that constrict blood vessels. These actions reduce blood pressure.
- **Angiotensin II** is a hormone that raises blood pressure. **Aldosterone** helps regulate salt excretion, which affects blood volume and blood pressure.

44.7 The Pattern of Circulation (page 953)

- 10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.**
- The **pulmonary circulation** connects the heart and the lungs; the **systemic circulation** connects the heart and the tissues. In the pulmonary circulation, the right ventricle pumps blood into the *pulmonary arteries*, which go to the lungs. Blood circulates through pulmonary capillaries in the lung and then is conducted to the left atrium by a *pulmonary vein*.
 - In the systemic circulation, the left ventricle pumps blood into the **aorta**, which branches into arteries leading to the body organs. After flowing through capillary networks within various organs, blood flows into veins that conduct it to the **superior vena cava** or **inferior vena cava**. These large veins return blood to the right atrium.

- The **coronary circulation** supplies the heart muscle with blood. The **hepatic portal system** circulates nutrient-rich blood through the liver.

44.8 The Lymphatic System (page 955)

- 11 Describe the inter-relationship between the structures and functions of the lymphatic system.**
- The **lymphatic system** helps maintain homeostasis of fluids by collecting interstitial fluid and returning it to the blood. The structure of the walls of *lymphatic vessels* allows them to collect excess interstitial fluid. **Lymph** is the clear fluid formed from interstitial fluid.
 - Lymphatic vessels conduct lymph to the blood. **Lymph nodes** are small masses of tissue that filter bacteria and harmful materials out of lymph.

44.9 Cardiovascular Disease (page 956)

- 12 Trace the progression of atherosclerosis and describe at least five risk factors for cardiovascular disease.**
- **Atherosclerosis** progresses as the inner walls of certain arteries become inflamed and the lumen of the artery becomes blocked by the accumulation of fatty deposits and cells that mediate inflammation. The blood supply of tissues served by these vessels becomes increasingly compromised.
 - Risk factors include elevated LDL-cholesterol levels in the blood, hypertension, cigarette smoking, diabetes mellitus, physical inactivity, and being overweight.

Test Your Understanding

Know and Comprehend

- Which of the following are most closely associated with oxygen transport? (a) red blood cells (b) platelets (c) neutrophils (d) basophils (e) lymphocytes
- The sinoatrial (SA) node (a) initiates diastole (b) conducts impulses directly to the muscle fibers of both ventricles (c) briefly delays transmission before the action potential continues into the ventricles (d) transmits action potentials directly into the atrial muscle fibers (e) consists of smooth muscle fibers
- A cardiac cycle (a) consists of one ventricular heartbeat (b) includes a systole (c) equals stroke volume multiplied by heart rate (d) includes a diastole (e) includes a systole and a diastole
- Blood pressure can be significantly affected by (a) cardiac output (b) peripheral resistance (c) blood volume (d) a, b, and c (e) a and b only
- Lymph forms from (a) fluid in the lymph nodes (b) blood serum (c) plasma combined with protein (d) fluid released by lymph nodes (e) interstitial fluid
- Norepinephrine (a) slows heart rate (b) is released in cardiac muscle by parasympathetic nerves (c) causes K^+ channels in cardiac muscle to open (d) decreases stroke volume (e) causes Ca^{2+} channels in cardiac muscle to open
- Baroreceptors (a) stimulate renin release (b) activate the renin-angiotensin-aldosterone pathway (c) stimulate sympathetic nerves (d) are stimulated by increased blood pressure (e) send messages to cardiac centers that increase blood pressure

Apply and Analyze

- Which sequence below describes an accurate sequence of blood flow? 1. pulmonary artery 2. pulmonary vein 3. left

- atrium 4. right atrium 5. pulmonary capillaries (a) 2, 1, 4, 3 (b) 3, 4, 2, 5 (c) 1, 5, 2, 3 (d) 4, 1, 5, 2 (e) 1, 5, 2, 4
- VISUALIZE** Draw a simple cross section of a vein, a capillary, and an artery. Label connective tissue, endothelium, and smooth muscle, if present. How does the structure of each of these vessels relate to its function?
- When the nerves to the heart are cut, the heart rate increases to about 100 contractions per minute. What does this increase indicate about regulation of the heart rate?

Evaluate and Synthesize

- EVOLUTION LINK** A heart divided into four chambers independently evolved in birds and mammals. What are the benefits of this adaptation?
- EVOLUTION LINK** How is the heart of a fish specifically adapted to its lifestyle?
- SCIENCE, TECHNOLOGY, AND SOCIETY** Explain the association between atherosclerosis and ischemic heart disease. Imagine that you were the Surgeon General of the United States. What types of programs would you advocate to decrease heart disease? Do you think that as a society we should invest resources into the development of stem cell therapies for more effective treatment of myocardial infarction?

45 The Immune System: Internal Defense

KEY CONCEPTS

- 45.1** The immune system recognizes and destroys foreign macromolecules, including those associated with pathogens, and abnormal cells (such as cancer cells).
- 45.2** Innate immunity provides general and immediate protection against pathogens, some toxins, and cancer cells.
- 45.3** Adaptive immunity includes cell-mediated immunity and antibody-mediated immunity.
- 45.4** In cell-mediated immunity, specific lymphocytes called T cells are activated; they release proteins that destroy cells infected with viruses or other intracellular pathogens.
- 45.5** In antibody-mediated immunity, specific lymphocytes called B cells are activated; they multiply and differentiate into plasma cells, which produce antibodies.
- 45.6** Cancer and some other diseases and disease-causing organisms—for example, HIV (the virus that causes AIDS)—compromise or overcome the immune system. Some immune responses, such as allergic responses, have negative effects on health.

PHOTO: Immune response to cancer cells. This color-enhanced SEM shows a macrophage (purple) engulfing a cancer cell (yellow).
Microworks/Medical Images

The **immune system**, our internal defense system, is made up of the molecules and cells that protect the body against foreign macromolecules, including disease-causing organisms, certain toxins, and cancer cells. Derived from the Latin for “safe,” the word *immune* refers to the early observation that when people recovered from smallpox and other serious infections, they were safe from contracting the same illness again.

Disease-causing organisms, called **pathogens**, include certain viruses, bacteria, fungi, protozoa, and worms. Pathogens enter the body with air, food, and water; during copulation; and through open wounds in the skin. The immune system recognizes pathogens and many types of toxins and rapidly responds to eliminate them. For example, *macrophages* act quickly to destroy invading bacteria. Macrophages and other cells of the immune system also destroy cancer cells (see photograph).

The immune system normally functions very effectively. However, some pathogens, and also cancer cells, sometimes evade or overcome the body's internal defenses, resulting in disease. Certain genetic mutations and some pathogens can prevent or compromise immune function. For example, HIV, the retrovirus that causes AIDS, destroys T cells, an important component of the immune system. At times, the immune system over-reacts, as in allergic reactions. At other times, immune responses are directed against our own tissues, resulting in *autoimmune disease* such as rheumatoid arthritis, ulcerative colitis, or multiple sclerosis. The immune system sometimes attacks when we would prefer it did not. For example, immune responses can destroy the cells of heart or kidney transplants.

Immunology, the study of internal defense systems of humans and other animals, is one of the most rapidly changing and exciting fields of biomedical research. The immune system is a collection of many types of cells and tissues scattered throughout the body. Effective cell signaling among these cells is critical. Cells of the immune system communicate

directly by means of their surface molecules and indirectly by releasing messenger molecules. Understanding the complex signaling systems of the immune system is a major focus of research. Investigators are also working to better understand the evolution of the immune system and how the immune system interacts with the microbiome.

One of the greatest accomplishments of immunologists has been the development of vaccines that prevent disease. Another has been developing techniques for successful tissue and organ transplantation. Sophisticated research strategies, such as gene transfer, have enabled immunologists to expand their knowledge of the cells and molecules that interact to generate immune responses. These techniques have led to the development of new approaches to the prevention and treatment of disease. Much has been learned, and many challenges lie ahead.

45.1 Evolution of Immune Responses

LEARNING OBJECTIVES

- 1 Distinguish between innate and adaptive immunity.
- 2 Compare, in general terms, the immune responses that have evolved in invertebrates and vertebrates.

Immunity is the ability to recognize and destroy foreign or dangerous macromolecules. The immune system distinguishes between *self* and *nonself*. Such recognition is possible because each individual is biochemically unique. Cells have surface proteins different from those on the cells of other species or even other individuals of the same species. An animal's immune system recognizes its own cells and can identify those of other organisms as foreign. The distinctive macromolecules of an invading pathogen stimulate the animal's defensive responses. For example, a single bacterium may have from 10 to more than 1000 distinctive macromolecules on its surface that an animal may recognize as foreign. The immune system also responds to danger signals from injured tissues, such as proteins released when cell membranes are damaged.

Two main types of immunity protect the body: innate and adaptive immunity (FIG. 45-1). **Innate immunity** consists of defenses that provide immediate, general protection against pathogens, parasites, some toxins and drugs, and cancer cells. Innate immune responses prevent most pathogens from entering the body and rapidly destroy those that do penetrate the outer defenses. For example, the cuticle or skin provides a physical barrier to pathogens that come in contact with an animal's body. *Phagocytosis* and *inflammation* are innate defenses that destroy bacteria when they manage to penetrate the outer defenses.

Adaptive immunity, also called **acquired immunity**, consists of specific defenses that target distinct macromolecules. Any molecule that cells of the immune system specifically recognize as foreign is called an **antigen**. Proteins are the most powerful antigens, but some polysaccharides and lipids are also antigenic. Adaptive immune responses are directed toward particular antigens. These responses typically include the production of **antibodies**, highly specific proteins that recognize and bind to specific antigens. An important characteristic of adaptive immune responses

is **immunological memory**, which means that the adaptive immune system “remembers” foreign or dangerous molecules. Immunological memory enables the body to respond more effectively to repeated encounters with the same molecules.

Immunologists do not yet understand how the immune system is signaled to *not* destroy foreign molecules that are harmless. Animals *manage* and are managed by their **microbiome**, which includes beneficial bacteria, archaea, and fungi that live on and in the body, including on the skin surface and in the digestive tract (see Chapters 25 and 47).

Invertebrates launch innate immune responses

An animal's first line of defense is its outer covering. Tough external skeletons, such as cuticles, shells, or chitinous exoskeletons, shield the bodies of nematodes, most mollusks, arthropods, and many other invertebrates (see Chapter 31). Cells in the outer layer of many invertebrates (cnidarians, annelids, and mollusks) produce mucus that traps and kills pathogens.

Recognition of nonself depends on **pattern recognition receptors (PRRs)** in the plasma membrane. PRRs, such as *Toll receptors* in *Drosophila*, recognize certain chemical compounds (or specific parts of compounds) on the surface of bacteria and other microbes as foreign. The chemical compounds that stimulate innate immune responses are called **pathogen-associated molecular patterns**, or **PAMPs**. Each group of microbes—viruses, gram-positive bacteria, and fungi—share certain PAMPs. For example, certain viruses have double-stranded RNA, and gram-positive bacteria have peptidoglycan.

All animal species studied have *phagocytes*, cells that move through the body engulfing and destroying bacteria and other foreign matter. When PRRs on phagocytes bind with PAMPs, innate immune responses are activated. For example, phagocytes then become more effective at destroying pathogens. These receptors may also transduce signals that stimulate inflammation.

Inflammation, also referred to as the *inflammatory response*, is one of the body's key responses to injury or infection in both invertebrates and vertebrates. During inflammation the body recruits white blood cells and plasma proteins from the blood to the location of an infection. *Phagocytosis* increases at the site of inflammation. Recall that **phagocytosis** is the process by which cells engulf microorganisms, foreign matter, or other cells (see Fig. 5-20). In mollusks, substances in the hemolymph (blood) enhance phagocytosis. Annelids are the only invertebrates known to have *natural killer cells*, a type of lymphocyte that destroys tumor cells and cells infected by viruses.

Invertebrates distinguish between their own cells and those of other species. For example, sponge cells have specific glycoproteins on their surfaces that enable them to recognize their own species. When cells of two different species are mixed, they sort themselves out according to species. When two different species of sponges are forced to grow in contact with each other, tissue is destroyed along the region of contact. Cnidarians (e.g., corals), annelids (e.g., earthworms), arthropods (e.g., insects), and echinoderms (e.g., sea stars) reject tissue grafted from other animals, even from the same species.

Pattern recognition receptors activate signal transduction pathways that lead to the production of **antimicrobial peptides**. These compounds inactivate or kill pathogens. Investigators have identified antimicrobial peptides in all eukaryotes (animals, plants, fungi) and prokaryotes (bacteria and archaea) that have been studied, suggesting an early common origin of these molecules. More than 2800 antimicrobial peptides have been described. When researchers inject an antigen into an insect, as many as 15 different antimicrobial peptides are produced within a few hours. These chemical compounds are very effective in part because of their small size (a dozen or fewer amino acids), which facilitates their rapid production and diffusion. Some antimicrobial peptides, called **defensins**, kill bacteria and fungi by punching holes in the plasma membrane. Defensins have been found in many types of animals and in some plants.

Certain cnidarians, arthropods, some echinoderms, and simple chordates (e.g., tunicates) appear to remember antigens for a short period. As mentioned earlier, immunological memory enables the body to respond more effectively when it encounters the same pathogens again. Researchers have discovered that shrimp are able to launch an adaptive immune response, called “specific immune priming.” During this response, phagocytic activity increased after the animals were vaccinated with a specific pathogen. Although certain invertebrates demonstrate

some specificity and memory, their immune responses are primarily innate responses.

Echinoderms and tunicates are the only invertebrates known to have differentiated white blood cells that perform limited immune functions. Investigators have identified two genes in the purple sea urchin that are very similar to vertebrate genes important in producing antibodies. Some invertebrates appear to have at least a limited capacity to launch adaptive immune responses.

Vertebrates launch both innate and adaptive immune responses

Like invertebrates, vertebrates depend on innate immunity for their initial defense against invading pathogens. However, their more recently evolved adaptive immune responses fine-tune the more general innate responses.

The lymphatic system that evolved in jawed vertebrates includes cells such as **lymphocytes**, white blood cells specialized to carry out immune responses, and organs such as lymph nodes (see Chapter 44). Very specific lymphocytes and antibodies are produced when the body is exposed to specific pathogens. Once exposed to foreign molecules, the adaptive immune system remembers them. In the discussion that follows, we focus on the vertebrate immune system.

CHECKPOINT 45.1

- What are two ways in which adaptive immunity differs from innate immunity?
- **CONNECT** In general, how are vertebrate immune responses similar to invertebrate responses? How are they different?

45.2 Innate Immune Responses in Vertebrates

LEARNING OBJECTIVE

- 3 Describe innate immune responses, including physical barriers; recognition by pattern recognition receptors; actions of phagocytes and other cells; actions of cytokines and complement; and the inflammatory response.

Innate immune responses include physical barriers, such as the skin; action by pattern recognition receptors; action of proteins such as *cytokines* and proteins that make up the *complement system*; actions by specialized cells, including phagocytes, dendritic cells, and natural killer (NK) cells; and the inflammatory response.

Physical barriers and chemical weapons stop most pathogens

A vertebrate's first line of defense is its skin, which blocks the entry of pathogens. In some species the skin is covered by horny scales or plates. The digestive (gastrointestinal) tract, respiratory passageways, urinary tract, and reproductive tracts all open to the outside of the body. The epithelial linings of these passageways are barriers between the outside environment and the inside of the body. Various mechanisms within epithelial barriers expel, trap, or destroy pathogens. For example, pathogens that enter the body with inhaled air may be filtered out by hairs in the nose or trapped in the sticky mucous lining of the respiratory tract. Once trapped, they are destroyed by phagocytes.

Physical barriers are equipped with chemical weapons. For example, the epithelium of the skin and of the digestive tract produces defensins. These antimicrobial peptides are present in the saliva of mammals and many other types of animals. Mucus contains a substance called *mucin*, which chemically destroys invaders. **Lysozyme**, an enzyme found in tears and other body fluids, attacks the cell walls of many gram-positive bacteria.

Mucus, tears, urine, and other body fluids flush pathogens out of the body. Invading bacteria must also compete with the populations of microbes that make up the microbiome. These resident microbes are normally not harmful and are essential to good health.

Blood clotting products aid the immune system by increasing vascular permeability and producing agents that help phagocytes. Some proteins produced during clotting can lyse invading gram-positive bacteria.

Pattern recognition receptors called **Toll-like receptors** are expressed on several types of cells. (Toll-like receptors are

homologous to the Toll receptors in *Drosophila*.) When activated, these receptors activate transcription factors that stimulate the expression of genes encoding important signaling molecules (e.g., cytokines).

Cells of the innate immune system destroy pathogens

Innate immune responses depend on the action of several types of cells, including phagocytes, natural killer cells, and dendritic cells. **Neutrophils**, the most common type of white blood cell (see Chapter 44), and *macrophages* are the main phagocytes in the body. A neutrophil can phagocytose about 20 bacteria before it becomes inactivated (perhaps by leaking lysosomal enzymes) and dies.

Macrophages are large phagocytes that develop from *monocytes*, a type of nongranular white blood cell. A macrophage can phagocytose about 100 bacteria during its life span (**FIG. 45-2**). Macrophages also release antiviral agents. Some macrophages patrol the body's tissues, engulfing damaged cells or foreign matter (including bacteria). Other macrophages stay in one place and destroy bacteria that pass by. For example, air sacs in the lungs contain large numbers of macrophages that destroy foreign matter entering with inhaled air.

Vertebrate macrophages have Toll-like receptors that recognize certain PAMPs and respond by producing cytokines. For example, a lipopolysaccharide found on gram-negative bacteria stimulates macrophages. In response, macrophages release cytokines that enhance the inflammatory response.

Can bacteria evade or counteract the phagocyte's attack? Many strategies have evolved in bacteria that protect them from their hosts. For example, the capsules of *Streptococcus pneumoniae* resist the actions of the phagocyte's lysosomal enzymes. Other bacteria

Figure 45-2 Phagocytosis: An innate immune response to infection

Macrophages are efficient warriors. This color-enhanced SEM shows a macrophage (large, deep blue cell) engulfing bacteria (small green cells).

release enzymes that destroy lysosomal membranes. The powerful lysosomal enzymes then spill out into the cytoplasm and may destroy the phagocyte. Bacteria and fungi may also form biofilms (see Chapters 6 and 25), which shield them from the immune cells and proteins. Individuals diagnosed with cystic fibrosis often develop chronic bacterial infections located within biofilms in the patients' respiratory systems.

Natural killer (NK) cells are large, granular lymphocytes that originate in the bone marrow. They account for about 10% of circulating lymphocytes. NK cells are active against tumor cells and cells infected with some types of viruses. They destroy target cells by both innate and adaptive (antibody-mediated) processes.

NK cells release cytokines as well as enzymes that destroy target cells. Some of these enzymes cause pores to form in the plasma membrane of the target cell. Other enzymes enter the cell and activate reactions that cause the cell to self-destruct by **apoptosis**, programmed cell death. Several cytokines stimulate NK cell activity. When NK cell levels are high, resistance to certain cancers may be strengthened. Psychological stressors may decrease NK cell activity and thus enhance tumor growth.

Biologists first identified **dendritic cells** in 1868 and then rediscovered them in 1973, but the small numbers of these cells made them hard to study until sophisticated techniques became available in the 1990s. Their name derives from their long cytoplasmic extensions called *dendrites* (not to be confused with the dendrites of neurons). Dendritic cells develop from precursor cells in the bone marrow and from monocytes.

Dendritic cells are strategically stationed in all tissues of the body that come into contact with the environment: the skin and the epithelial linings of the digestive, respiratory, urinary, and vaginal passageways. When pathogens infect a tissue, PAMPs activate dendritic cells. One type of dendritic cell responds to viral infection. Dendritic cells produce *interferons*, cytokines that are antiviral. Certain types of activated dendritic cells capture microbial antigens by phagocytosis or by receptor-mediated endocytosis (see Chapter 5).

Cytokines are important signaling molecules

Cells of the immune system secrete a remarkable number of regulatory and antimicrobial peptides and proteins. Two major groups of molecules that are critical in innate defense responses are cytokines and complement. **Cytokines** are a large, diverse group of peptides and proteins (most are glycoproteins) that serve as important signaling molecules and perform regulatory functions. The same kinds of cytokines can be produced by many different types of cells. Also, a cytokine may affect many different kinds of cells. Just as the functions of innate and adaptive immune responses overlap, the actions of cytokines of these subsystems also overlap. For example, cytokines produced by cells such as macrophages can activate lymphocytes involved in adaptive immune responses.

Cytokines help regulate the intensity and duration of immune responses. They are also important in regulating many other biological processes, such as cell growth, repair, and cell activation. Cytokines bind to specific membrane receptors on target cells. These signaling molecules can act as *autocrine agents*,

affecting the very cells that produce them, or as *paracrine agents*, regulating the activity of nearby cells (see Chapter 49). When produced in large amounts, some cytokines act as hormones that circulate in the blood and affect distant tissues. Biologists name the types of cytokines for their function or origin. We discuss several examples, including *interferons*, *tumor necrosis factors*, *interleukins*, and *chemokines*.

When infected by viruses or other intracellular parasites (some types of bacteria, fungi, and protozoa), certain cells respond by secreting cytokines called **interferons**. *Type I interferons* are produced by either macrophages or *fibroblasts*, cells that produce the fibers of connective tissues. Type I interferons inhibit viral replication and activate NK cells that have antiviral actions. Viruses produced in cells exposed to Type I interferons are not very effective at infecting other cells. Interestingly, even though Type I interferons are produced as part of the innate immune response, once released they can regulate the action of certain cells of the adaptive immune response. This interaction of innate and adaptive immune mechanisms is an example of the power and complexity of the immune system.

Type II interferon (also called IFN-gamma) is critical in both innate and adaptive immunity. In innate immunity Type II interferon stimulates macrophages to destroy tumor cells and host cells that have been infected by viruses. (The interferon activates transcription of genes that encode enzymes needed to produce antimicrobial compounds in lysosomes.)

Since their discovery in 1957, interferons have been the focus of a great deal of research. Pharmaceutical companies now use recombinant DNA techniques to produce large quantities of some interferons. The U.S. Food and Drug Administration has approved interferons for treating several diseases, including hepatitis B and hepatitis C, genital warts, several types of cancer (e.g., leukemia), a type of multiple sclerosis, and AIDS-related Kaposi's sarcoma.

In response to gram-negative bacteria, certain other pathogens, or some tumors, **tumor necrosis factor (TNF)** stimulates immune cells to initiate an inflammatory response. In fact, TNF was so named because it was first identified as a compound that destroyed tumor cells. TNF is secreted mainly by macrophages and by *T cells*, a type of lymphocyte. In severe infections, large amounts of TNF are produced. TNF is then circulated in the blood and can have widespread effects. For example, it acts on the hypothalamus, inducing fever.

Sometimes infection by gram-negative bacteria, such as *Salmonella typhi*, results in the release of large amounts of TNF and other cytokines. The result is a cascade of reactions leading to *septic shock*, a potentially fatal condition that may involve high fever and malfunction of the circulatory system. Thus, cytokines can sometimes have harmful effects.

Interleukins are a diverse group of cytokines secreted mainly by macrophages and lymphocytes. Interleukins are numbered according to their order of discovery. They regulate interactions between white blood cells, such as lymphocytes and macrophages, and other cells. *Interleukin-1 (IL-1)* functions with TNF in mediating inflammation. *Interleukin-12 (IL-12)* stimulates NK cells as well as T cells to produce IFN-gamma. Some interleukins have widespread effects. During infection, IL-1 can reset the body's thermostat in the

Key Point

During the inflammatory response, capillaries dilate and become more permeable, bringing more phagocytes to the infected area; phagocytosis increases.

Figure 45-3 Overview of the inflammatory response

When skin is injured, bacteria (and other pathogens) enter the tissues. Tissue injury activates a clotting factor in the blood that turns on three molecular pathways in the plasma. Some of the molecules produced dilate blood vessels and increase capillary permeability.

PREDICT If left untreated, how might your foot look and feel the day after stepping on a nail?

hypothalamus, resulting in fever and its symptoms. The overproduction of certain interleukins has been associated with clinical disease, including atherosclerosis.

Chemokines, a large group of cytokines, are signaling molecules that attract, activate, and direct the movement of various cells of the immune system. For example, they regulate the migration of white blood cells from the blood to the tissues. Some chemokines are produced in response to infection and are mediators of the inflammatory response.

Complement promotes destruction of pathogens and enhances inflammation

Phagocytes secrete cytokines that activate the *complement system*. **Complement**, so named because it “complements” the action of other defensive responses, consists of more than 20 proteins present in plasma and other body fluids. Similarities in complement proteins in many species, including horseshoe crabs, sea urchins, tunicates, and mammals, suggest that these

molecules evolved millions of years ago and have been highly conserved.

Normally, complement proteins are inactive until the body is exposed to an antigen. Certain pathogens activate the complement system directly. In other cases, the binding of an antigen and antibody stimulates activation. Complement activation involves a cascade of reactions; each component acts on the next in the series. Proteins of the complement system then work to destroy pathogens.

Complement proteins are active against many antigens, and their actions are not specific: they (1) lyse viruses, bacteria, and other cells; (2) coat pathogens, making them less “slippery” so that macrophages and neutrophils phagocytose them more easily; (3) attract white blood cells to the site of infection, a process called *chemotaxis*; and (4) bind to specific receptors on cells of the immune system, stimulating specific actions, such as secreting regulatory molecules and enhancing the inflammatory response.

Inflammation is a protective response

The **inflammatory response**, or *inflammation*, is one of the body’s key responses to infection or injury. Tissue injury caused by pathogen invasion or physical injury activates a clotting factor in the blood plasma that turns on three different

interconnecting molecular cascades in the plasma, including the clotting cascade. Many of these reactions generate molecules—for example, the peptide *bradykinin*—that mediate the inflammatory process. These plasma mediators dilate blood vessels and increase capillary permeability (FIGS. 45-3 and 45-4). Many cytokines signal white blood cells to launch the inflammatory response, and some cytokines help regulate the process. Inflammation also activates the complement system. The clinical characteristics of inflammation are heat, redness, edema (swelling), and pain.

The inflammatory response includes three main processes.

1. **Vasodilation.** Macrophages and **mast cells** stationed in the tissues respond rapidly to damaged tissue or infection. Mast cells, which are found in most tissues close to blood vessels, release **histamine**, cytokines, and other compounds that dilate blood vessels in the affected area. Expanded blood vessel diameter brings more blood to the

(a) Mast cells in the tissue secrete cytokines, histamine, and other compounds that increase capillary permeability and dilate blood vessels. Certain cytokines attract phagocytic cells. Macrophages and neutrophils in the infected area engulf and destroy bacteria. Macrophages also secrete cytokines that recruit additional neutrophils.

Figure 45-4 The inflammatory response

The body reacts to tissue injury, infection, or exposure to certain toxins with an inflammatory response.

Bacteria are represented by yellow rods, cytokines by green dots, histamines by orange squares, and other mast cell secretions by orange dots.

area. The increased blood flow warms the skin and reddens skin that contains little pigment.

- 2. Increased capillary permeability.** Histamine and other compounds released by mast cells increase capillary permeability. Fluid and antibodies leave the circulation and enter the tissues. As the volume of interstitial fluid increases, *edema* occurs. The edema, along with the action of certain enzymes in the plasma, causes the pain that characterizes inflammation.
- 3. Increased phagocytosis.** Increased blood flow brings large numbers of neutrophils and other phagocytic cells to the inflamed region within a few hours of tissue injury or infection. The phagocytes migrate out of the capillaries and into the infected tissues. Macrophages secrete chemokines and other cytokines that recruit and activate additional neutrophils. One of the main functions of inflammation is increased phagocytosis.

Although the inflammatory response begins as a local response, sometimes the entire body may become involved.

Fever, a common clinical symptom of widespread inflammation, helps the body fight infection. Elevated body temperature increases phagocytosis and interferes with the growth and replication of microorganisms. Fever breaks down lysosomes, destroying cells infected by viruses. Fever also promotes the activity of certain lymphocytes. A short-term, low fever speeds recovery.

The inflammatory response is vital in overcoming infection, but it can also cause tissue damage and disease. *Chronic inflammation* contributes to many chronic diseases. For example, inflammation has been linked with atherosclerosis, rheumatoid arthritis, Crohn's disease, diabetes, Alzheimer's disease, and cancer. Although we do not yet understand the details, chronic inflammation appears to occur when homeostatic mechanisms that normally turn off the inflammatory response do not function appropriately. Investigators have identified several risk factors for chronic inflammation, including prolonged infections, cigarette smoking, gum disease, and obesity.

(b) Large numbers of monocytes and phagocytic cells pass through the now dilated, permeable capillaries into the infected area. Monocytes develop into macrophages. Phagocytosis increases.

CHECKPOINT 45.2

- What is the function of pattern recognition receptors?
- **PREDICT** What would happen if you had no NK cells? What would happen if you had no macrophages?
- Describe two functions of cytokines. What are two functions of complement proteins?
- **VISUALIZE** Draw a diagram illustrating the main steps in the inflammatory response.

45.3 Adaptive Immune Responses in Vertebrates

LEARNING OBJECTIVES

- 4** Contrast cell-mediated and antibody-mediated immunity and give an overview of each process.
- 5** Describe the functions of the specialized cells of the adaptive immune system and of the major histocompatibility complex.

Adaptive immune responses are also referred to as *acquired immunity*. In contrast to innate immune mechanisms that are always present and ready to respond to infection, adaptive

immune responses develop in response to an infection and *adapt* to the specific pathogens invading the body. These immune responses are highly specific for distinct macromolecules.

While innate immune responses destroy pathogens and prevent the spread of infection, the body mobilizes its adaptive immune responses. It takes several days to activate adaptive immune responses, but once in gear, these mechanisms are extremely effective. As discussed earlier, adaptive immune responses are precisely targeted to destroy specific antigens, and they have immunological memory. Two types of adaptive immune responses are *cell-mediated immunity* and *antibody-mediated immunity*.

Many types of cells are involved in adaptive immune responses

The main types of cells of the adaptive immune system are shown in **FIGURE 45-5**. Two key cell types that participate in adaptive immune responses are lymphocytes and *antigen-presenting cells*. Phagocytes and many other cells important in innate immune responses also participate in specific responses. **Eosinophils**, for example, are white blood cells that release proteins, including cytokines, from their granules. Some of these cytokines are important in adaptive immune responses. Eosinophils also release proteins that are toxic to parasitic worms (the life cycles of some parasitic worms are described in Chapter 31).

Cells important in adaptive immune responses include antigen-presenting cells (macrophages and dendritic cells) and lymphocytes (T cells and B cells). These cells interact through complex signaling.

Figure 45-5 Some key cells in adaptive immune responses

Recall that macrophages and dendritic cells also have vital roles in innate immunity.

PREDICT What effect would multiple myeloma (a bone marrow cancer in which malignant plasma cells accumulate in the bone marrow) have on the production of antigen-presenting cells and lymphocytes?

Lymphocytes are important in both adaptive and innate immunity. Natural killer cells (NK cells) were discussed in the previous discussion of innate immunity. Recall that NK cells are lymphocytes that kill virally infected cells and tumor cells. **T lymphocytes**, commonly called **T cells**, and **B lymphocytes**, known as **B cells**, recognize antigens and are key cells in adaptive immunity. All lymphocytes develop from stem cells in the bone marrow. B cells complete their development in the adult bone marrow. T cells mature in the **thymus gland** (from which the *T* in their name derives). Large numbers of mature lymphocytes reside in lymph organs, including the spleen, lymph nodes, tonsils, and other lymph tissues strategically positioned throughout the body.

Although T cells and B cells are similar in appearance when viewed with a light microscope, sophisticated techniques such as fluorescence microscopy demonstrate that these cells can be differentiated by their unique cell-surface macromolecules. T cells and B cells have different functions and life histories and tend to locate in (or “home” to) separate regions of the spleen, lymph nodes, and other lymph tissues.

T cells are responsible for cell-mediated immunity

T cells are the body’s cellular soldiers. T cells travel to the site of infection and attack body cells infected by invading pathogens as well as foreign cells (such as those introduced in tissue

grafts or organ transplants). T cells also destroy cells altered by mutation (cancer cells).

On their way from the bone marrow to the lymph tissues, T cells are processed in the thymus gland. As T cells move through the thymus, they divide many times and develop specific surface proteins with distinctive receptor sites. The thymus makes T cells *immunocompetent*, capable of producing an effective immune response after exposure to an antigen.

The T-cell population undergoes positive and negative selection. In *negative selection*, T cells in the thymus that react to self-antigens undergo apoptosis. Immunologists estimate that more than 90% of developing T cells are negatively selected in this way.

In *positive selection*, T cells are allowed to mature if they recognize self-antigens and bind with foreign antigens. These T cells differentiate and leave the thymus to take up residence in other lymph tissues or to launch immune responses in infected tissues. By selecting only appropriate T cells, the thymus gland ensures that T cells can distinguish between the body's own molecules and foreign antigens.

Most T cells in the thymus differentiate just before birth and during the first few months of postnatal life. If the thymus is removed before this processing takes place, an animal does not develop cell-mediated immunity. If the thymus is removed after that time, cell-mediated immunity is less seriously impaired.

T cells are distinguished by the **T-cell receptor (TCR)**, which recognizes specific antigens. Two main populations of T cells are T cytotoxic cells and T helper cells. **T cytotoxic (T_C) cells** are also known as *CD8 cells* because they have a glycoprotein designated CD8 on their plasma membrane surface. T_C cells recognize and destroy cells with foreign antigens on their surfaces. Their target cells include virus-infected cells, cancer cells, and foreign tissue grafts.

T helper cells (T_H cells), also known as *CD4 cells*, have a surface glycoprotein designated CD4. T_H cells secrete cytokines that activate B cells, T cells, and macrophages. **Regulatory T cells**, also known as T_{reg} , are a subpopulation of T_H cells. Regulatory T cells help regulate immune responses by suppressing the function of certain T cells and by interacting with mature B cells (plasma cells). After an infection, **memory T cells** (both memory T_C cells and memory T_H cells) remain in the body.

B cells are responsible for antibody-mediated immunity

B cells mature into **plasma cells**, which produce specific antibodies. Antibodies bind to specific antigens, neutralizing them or marking them for destruction. Antibody-mediated immunity is one of the body's chief chemical defense strategies.

Each B cell is genetically programmed to code for a glycoprotein receptor that can bind with a specific type of antigen. When a B cell comes into contact with an antigen that binds to its receptors, the B cell becomes activated. B-cell activation is a complex process that typically requires the participation of a T helper cell.

Once activated, a B cell divides rapidly to form a clone of identical cells. Some of the cloned B cells differentiate into plasma cells, which produce antibodies. Other activated B cells become **memory B cells**. A plasma cell can produce more than ten million molecules of antibody per hour! The antibody binds

to the antigen that originally activated the B cells. Plasma cells continue to produce small amounts of antibody for months or years after the body overcomes an infection. Researchers at the University of Pennsylvania recently reported that regulatory T cells interact with and support plasma cells in the bone marrow. Without T cells, the plasma cells disappear.

Antigen-presenting cells activate T helper cells

Macrophages, dendritic cells, and B cells function as “professional” **antigen-presenting cells (APCs)** that display foreign antigens as well as their own surface proteins. APCs are inactive until their pattern recognition receptors recognize PAMPs on pathogens. Once activated, an APC ingests the pathogen. Lysosomal enzymes inside the APC degrade most bacterial antigens, but not all. The APC displays fragments of the foreign antigens on its cell surface in association with a type of self-molecule (class II MHC, discussed later). The activated APC expresses additional signaling molecules, called *co-stimulatory molecules*, along with the displayed antigen. These fully functional APCs present displayed antigens to T cells.

In addition to their function as APCs, macrophages secrete more than 100 different compounds, including cytokines and enzymes that destroy bacteria. When stimulated by bacteria, macrophages secrete interleukins that activate B cells and certain T cells. We have seen that interleukins also promote innate immune responses such as fever.

Receptors on dendritic cells bind antigens of microbes. Dendritic cells take these antigens, process them, and display antigen fragments on their cell surface. This is how they become APCs. The dendritic cells leave the epithelial lining and, guided by chemokines, migrate to the lymph nodes. Co-stimulatory molecules, along with the displayed antigen, attract and activate specific T cells capable of responding to the antigen. Thus, dendritic cells are specialized to bind, process, transport, and present antigens to T cells.

The major histocompatibility complex is responsible for recognition of self

The ability of the vertebrate immune system to distinguish self from nonself depends largely on a cluster of closely linked genes known as the **major histocompatibility complex (MHC)**. The human MHC is also referred to as **human leukocyte antigen complex (HLA)**. (We use the designations MHC and HLA interchangeably in this chapter.) The HLA consists of a group of loci on chromosome 6. The HLA genes are polymorphic (variable). Within the population there are multiple alleles for each locus. About 10,000 alleles have been identified. (Note that MHC and HLA refer to both the loci and to the membrane proteins they encode.)

The HLA genes encode HLA membrane proteins referred to as self-antigens. Because there are so many alleles, the HLA membrane proteins differ in chemical structure, function, and tissue distribution. With so many possible combinations, no two people, except identical twins, are likely to have all the same HLA proteins on their cell membranes. The more closely related two individuals are, the more HLA alleles they have in

common. You can think of your HLA proteins as a biochemical “fingerprint.”

There are three main Class I HLA loci, which encode glycoproteins expressed on the surface of most nucleated cells. These antigens bind with foreign antigens from viruses or other pathogens processed within the cell to form a foreign antigen–class I HLA glycoprotein complex. The cell displays this complex on its surface and presents it to T_C cells. Thus, any infected cell can function as an antigen-presenting cell, which can activate certain T_C cells or can be instructed to self-destruct.

Six main class II HLA loci encode glycoproteins expressed primarily on “professional” APCs: dendritic cells, macrophages, and B cells. These class II HLA antigens combine with foreign antigen from bacteria, and the APC then presents the complex to T_H cells. Class III HLA loci encode many secreted proteins involved in the immune response, including components of the complement system and TNFs.

CHECKPOINT 45.3

- **CONNECT** How are cell-mediated immunity and antibody-mediated immunity alike? How are they different?
- What is the function of antigen-presenting cells? Identify three types of antigen-presenting cells.
- **PREDICT** Which kidney transplant would more likely be successful—a transplant from an unknown donor or a transplant between first cousins? Support your answer. (Hint: Consider the HLA.)

45.4 Cell-Mediated Immunity

LEARNING OBJECTIVE

6 Describe the sequence of events in cell-mediated immunity.

T cells and APCs (mainly dendritic cells and macrophages) are responsible for **cell-mediated immunity**. T cells destroy cells infected with viruses, as well as macrophages that have ingested “smart” bacteria. These bacteria escape from the vesicles in which they are enclosed during phagocytosis. They escape destruction by lysosomal enzymes by “hiding” in the cytoplasm of macrophages. T cells destroy cells that have been altered in some way, such as cancer cells. They also destroy the cells of foreign grafts such as a transplanted kidney or liver.

How do T cells know which cells to target? T cells do not recognize antigens unless they are presented properly. Recall that when a virus (or other pathogen) infects a cell, some of the viral protein is broken down to peptides and displayed with class I MHC molecules on the cell surface. Only T cells with receptors that bind to the specific antigen–MHC complex become activated.

Recall that there are two general populations of T cells: T_H cells and T_C cells. Each T_H cell expresses molecules of the glycoprotein called CD4, and each T_C cell expresses CD8

molecules. Within each general T cell population there are thousands of different antigen specificities that the T-cell receptors (TCRs) can recognize. Activation of T_H cells, for example, occurs when phagocytic cells digest antigen and parts of the antigen are placed within their surface MHC complexes. They then present these antigens to the TCR on T_H cells as part of a foreign antigen–class II MHC glycoprotein complex.

Once activated by the foreign antigen–MHC class II antigen complex displayed on the surface of APCs, the activated T_H cells secrete interleukin 2. This cytokine is a growth factor that stimulates the activated cells to proliferate. The T_H cells divide several times, giving rise to a clone of T_H cells (FIG. 45-6). This process is called **clonal expansion**.

Some of the T_H cells produced migrate to the site of infection. These cells can produce many different types of cytokines. Some attract macrophages to the site of infection and promote the destruction of intracellular pathogens. Others function mainly in promoting antibody-mediated immunity.

Each T_C cell expresses the CD8 molecule, as well as more than 50,000 identical TCRs, on its surface. The TCRs bind to one specific type of antigen. T_C cells recognize antigens presented to them as part of a foreign antigen–class I MHC glycoprotein complex. Generally, fewer than 1 in 100,000 T cells have the same antigen specificity and can respond. However, after clonal expansion as many as 1 in 10 T_C cells may be specific for the targeted antigen. T_C -cell activation requires at least two signals in addition to the presented antigen: a co-stimulatory signal and an interleukin signal. Once activated, a T_C cell increases in size and gives rise to a clone of many effector T_C cells.

Effector T_C cells make up the cell infantry. They leave the lymph nodes and make their way to the infected area, where they destroy target cells within seconds after contact. When a T_C cell combines with antigen on the surface of the target cell, it destroys the cell in much the same way that NK cells destroy their target cells. The T_C cell secretes perforins that perforate the plasma membrane of the target cell. Granzymes then induce the cell to self-destruct by apoptosis. After releasing cytotoxic substances, the T cell disengages itself from its victim cell and seeks out a new target.

The sequence of events for production and function of T_C cells in cell-mediated immunity can be summarized as follows:

virus invades body cell → infected cell displays foreign antigen–MHC class I antigen complex → specific T_C cell is activated by this complex → clone of T_C cells produced → effector T_C cells migrate to area of infection → T_C cells are stimulated by cytokines released by T_H cells → T_C cells release enzymes that destroy target cells

CHECKPOINT 45.4

- **CONNECT** How do APCs, T_C cells, and T_H cells work together in cell-mediated immunity?

T cells and APCs are responsible for cell-mediated immunity.

45.5 Antibody-Mediated Immunity

LEARNING OBJECTIVES

- Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen-antibody complexes on pathogens.
- Describe the basic structure and function of an antibody and explain the basis of antibody diversity.
- Describe the basis of immunological memory and contrast secondary and primary immune responses.
- Compare active and passive immunity, and give examples of each.

We have discussed two types of molecules that recognize specific antigens: T-cell receptors and MHC molecules (HLA in humans). Here we turn our attention to the third type, antibodies. B cells are responsible for **antibody-mediated immunity**.

A given B cell can produce many copies of one specific antibody. Antibody molecules serve as cell-surface receptors that combine with antigens. Only a B cell with a receptor complementary in shape to a particular antigen can bind that antigen. The antigen enters the B cell by receptor-mediated endocytosis (see Chapter 5). The antigen is then degraded into peptide fragments, and the B cell displays peptide fragments together with MHC protein class II on its surface.

In most cases, the activation of B cells involves APCs and T_H cells (FIG. 45-7). T_H cells stimulate B cells to divide and produce antibodies. However, the T_H cell itself must first be activated. T_H cells do not recognize an antigen that is presented alone. An APC must present the antigen as part of a foreign antigen-class II MHC complex on its surface. When an APC displaying a foreign antigen-MHC complex contacts a T_H cell with complementary T-cell receptors, a complicated interaction occurs. Multiple chemical

Figure 45-6 Cell-mediated immunity

When activated by a foreign antigen-MHC complex presented by an APC and by cytokines, a T_H cell divides and gives rise to a clone of T_H cells. T_C cells are also activated by antigens presented on the surfaces of infected cells, and they also form a clone. Both types of T cells migrate to the site of infection. T_H cells release cytokines that stimulate T_C cells and activate macrophages, which then phagocytose pathogens. T_C cells release proteins that destroy infected cells. There are many receptors on the surface of each T cell and each B cell. For simplicity, only one receptor per cell is shown.

CONNECT What types of cells can function as APCs?

Figure 45-7 B-cell activation

This figure is a detailed illustration of the first four steps in Figure 45-8. There are many receptors on the surface of each T cell and each B cell. For simplicity, only one receptor per cell is shown.

signals are sent back and forth between cells. For example, the APC secretes interleukins, such as IL-1, that activate T_H cells.

B cells serve as APCs to T cells. An activated T_H cell binds with the foreign antigen-MHC complex on the B cell. The T_H cell then releases interleukins, which together with antigen activate the B cell.

Once activated, a B cell divides by mitosis, giving rise to a clone of identical cells (FIG. 45-8). This clonal expansion in response to a specific antigen is known as *clonal selection* (discussed later). The cloned B cells mature into two types of cells: plasma cells that secrete antibodies and memory B cells. Antibodies are specific to the antigen that activated the original B cell. It is important to remember that the specificity of the clone is determined *before* the B cell encounters the antigen.

Unlike T cells, most plasma cells remain in the lymph nodes. The antibodies they secrete pass out of the lymph tissues and make their way via the lymph and blood to the infected area. The secreted antibody is a soluble form of the glycoprotein receptor of the activated B cell.

The sequence of events in antibody-mediated immunity can be summarized as follows:

a pathogen invades the body → an APC phagocytoses the pathogen → foreign antigen-MHC complex is displayed on APC surface → T_H cell binds with foreign antigen-MHC complex → activated T_H cell interacts with a B cell that displays the same antigen → B cell is activated → clone of B cells produced → B cells differentiate, becoming plasma cells → plasma cells secrete antibodies → antibodies form complexes with pathogen → pathogen is destroyed

Some activated B cells do not differentiate into plasma cells. Instead, they become memory B cells (discussed in a later section).

A typical antibody consists of four polypeptide chains

An antibody molecule, also called **immunoglobulin (Ig)**, has several functions. It combines with antigen and activates processes that destroy the bound antigen. For example, an antibody may stimulate phagocytosis. Note that an antibody does not destroy an antigen directly; rather, it *labels* the antigen for destruction. When it is attached to the B-cell surface, an antibody molecule serves as the B-cell receptor for antigen.

In a Y-shaped antibody molecule, the tail of the Y is called the *Fc fragment* (*c* indicates that this fragment crystallizes during cold storage). The Fc fragment binds with receptors on phagocytes and other cells of the immune system. This region of the antibody molecule also binds with molecules of the complement system. The two arms of the Y are referred to as *Fab fragments* (*Fab* stands for *fragment, antigen-binding*). The tips of the Fab fragments bind with antigen (FIG. 45-9). The Y shape permits the antibody molecule to combine with two antigen molecules, resulting in the formation of *antigen-antibody complexes*.

Each antibody molecule consists of four polypeptide chains: two long chains, called *heavy chains*, and two short

Key Point

B cells, APCs, and T_H cells are responsible for antibody-mediated immunity.

Figure 45-8 Antibody-mediated immunity

A specific B cell may be activated when a specific antigen binds to receptors on its surface. Typically, the B cell also requires cytokine stimulation from an activated T_H cell (see Fig. 45-7). Once activated, the B cell divides and produces a clone of B cells. Many of these B cells differentiate and become plasma cells that secrete antibodies. Others become memory B cells. Plasma cells remain in the lymph tissues, but the antibodies they secrete are transported to the site of infection by the blood or lymph. After the infection has been overcome, memory B cells remain in the tissues. There are many receptors on the surface of each T cell and each B cell. For simplicity, only one receptor per cell is shown.

PREDICT What would be the effect on immune responses if T_C cells collected in the lymph tissue as plasma cells do?

(a) The antibody molecule is composed of two light chains and two heavy chains joined by disulfide bonds. The constant (C) and variable (V) regions of the chains are labeled.

(b) The Fab portion of the antibody binds to antigen. The Fc portion of the molecule binds to a cell of the immune system (not shown). Antigen-antibody complexes directly inactivate pathogens and increase phagocytosis. They also activate the complement system.

Figure 45-9 Antibody structure and function

Antibodies combine with antigens to form antigen-antibody complexes. As shown, these complexes destroy or promote the destruction of pathogens in a variety of ways.

chains, called *light chains*. Each chain has a constant region and a variable region. In the *constant (C) region* of the heavy chains, the amino acid sequence is constant within a particular immunoglobulin class. The C region of the heavy

chains forms the tail of the Y part of the antibody molecule. You can think of this C region as the handle portion of a door key.

The *variable (V) region* has a unique amino acid sequence, like the pattern of bumps and notches on the part of a key that fits into a lock. At its variable regions, the antibody folds three-dimensionally, assuming a shape that enables it to combine with a specific antigen. When they meet, antigen and antibody fit together somewhat like a lock and key. They must fit in just the right way for the antibody to be effective (FIG. 45-10).

The specific part of the antigen molecule that is recognized by an antibody or T-cell receptor is called an *antigenic determinant*, or *epitope*. An antigen may have many antigenic determinants on its surface; some have hundreds. Antigenic determinants often differ from one another, so several different kinds of antibodies can combine with a single antigen. A given antibody can bind with different strengths, or *affinities*, to different antigens. In the course of an immune response, higher affinity antibodies are generated. This increase in affinity occurs because as activated B cells are replicated, mutations occur in genes that encode the antibodies. Cells with antibodies that bind more tightly are selected during the ongoing immune response—a striking example of microevolution in action.

Antibodies are grouped in five classes

Antibodies are grouped in five classes, defined by unique amino acid sequences in the C regions of the heavy chains. The classes are named using the abbreviation *Ig* for *immunoglobulin* and are designated IgG, IgM, IgA, IgD, and IgE. In humans about 75% of the circulating antibodies belong to the *IgG* class; they are part of the gamma globulin fraction of the plasma. *IgM* is the first antibody that humans make in an immune response. IgG and IgM share some functional properties. Both interact with macrophages and activate the complement system. They defend against many pathogens carried in the blood, including bacteria, viruses, and some fungi. IgG is the antibody that crosses the *placenta* (the organ of exchange between mother and developing fetus) and protects the fetus and, later, the newborn baby.

IgA, present in mucus, tears, saliva, and breast milk, prevents viruses and bacteria from attaching to epithelial surfaces. This immunoglobulin, which defends against inhaled or ingested pathogens, is strategically secreted into the respiratory, digestive, urinary, and reproductive tracts. Like IgM, *IgD* is an important immunoglobulin on the B-cell surface. It has a critical role in maturation of B cells and helps activate B cells following antigen binding. IgD has a low concentration in plasma (less than 1% of circulating antibodies).

IgE, which has an even lower plasma concentration than IgD, defends the body against invading parasitic worms. IgE also plays a role in allergic reactions. It binds to mast cells, which contain histamine and other potent signaling molecules. These chemicals are released when an antigen binds to IgE on a mast cell. Histamine triggers many allergy symptoms, including inflammation.

(a) A portion of the antigenic determinant (red) fits into a groove in the antibody molecule.

(b) The antigen–antibody complex has been pulled apart to show its structure.

Figure 45-10 An antigen–antibody complex

The components of an antigen–antibody complex fit together as shown in this computer simulation of their molecular structure. Antigen lysozyme, *green*; heavy chain of the antibody, *blue*; light chain, *yellow*.

Antigen–antibody binding activates other defenses

Antibodies mark a pathogen as foreign by combining with an antigen on its surface. Generally, several antibodies bind with several antigens, creating a mass of clumped antigen–antibody complexes. The combination of antigen and antibody activates several defensive responses (see Fig. 45-9).

1. The antigen–antibody complex may inactivate the pathogen or its toxin. For example, when an antibody attaches to its surface, a virus may lose the ability to attach to a host cell.
2. The antigen–antibody complex stimulates phagocytic cells to ingest the pathogen.
3. Antibodies of the IgG and IgM groups work mainly through the complement system.

When antibodies combine with a specific antigen on a pathogen, complement proteins destroy the pathogen. IgG molecules have an Fc fragment that binds Fc receptors; these receptors are expressed on many cells, including macrophages and neutrophils. When an antibody molecule is bound to a pathogen and the Fc portion of the antibody binds with an Fc receptor on a phagocyte, the pathogen is more easily destroyed.

The immune system responds to millions of different antigens

How can the immune system recognize every possible antigen, even those produced by newly mutated viruses never before encountered during the evolution of our species? In the 1950s, Danish researcher Niels Jerne of the Basel Institute for Immunology in Basel, Switzerland; David Talmage of the University of Chicago; and Frank Macfarlane Burnet of the Walter and Eliza Hall Institute for Medical Research in Melbourne, Australia, developed the **clonal selection** hypothesis. This hypothesis proposes that before a lymphocyte ever encounters an antigen, the lymphocyte has specific receptors for that antigen on its surface. (Jerne and Burnet later were awarded Nobel Prizes in Physiology or Medicine for their work in immunology.)

When an antigen binds to a matching receptor on a lymphocyte (T cell), it activates the lymphocyte, which then gives rise to a clone of cells with identical receptors. A problem with this hypothesis, when it was initially proposed, was its suggestion that our cells must contain millions of separate antibody genes, each coding for an antibody with a different specificity. Although each human cell has a large amount of DNA, it is not enough to provide a different gene to encode each of the millions of possible specific antibody molecules.

An explanation for how the immune system could have so many different specificities came later. In 1965, W. J. Dreyer of the Institute of Biochemistry at the University of Zurich, Switzerland, and Joe Claude Bennett of the University of Alabama at Birmingham suggested that the C region and the V region of an immunoglobulin are encoded by two separate genes. Their hypothesis was at first rejected by many biologists because it contradicted the prevailing hypothesis that one gene codes for one polypeptide.

The technology needed to test Dreyer and Bennett's hypothesis was not immediately available, and it was not until 1976 that Susumu Tonegawa of the Massachusetts Institute of Technology and his colleagues demonstrated that separate genes encode the V and C regions of immunoglobulins. Tonegawa further showed that three separate families of genes code for immunoglobulins and that each gene family contains a large number of DNA segments that code for V regions. Recombination of these DNA segments during the differentiation of B cells is responsible for antibody diversity. Tonegawa was awarded the 1987 Nobel Prize in Physiology or Medicine for his work, which transformed the emerging science of immunology.

We now understand that in undifferentiated B cells, gene segments are present for a number of different V regions, for one or more junction (J) regions, and for one or more different C regions (**FIG. 45-11**). Rearrangement of these DNA segments produces an enormous number of potential combinations. Millions of different types of B (and T) cells are produced. By chance, one of those B cells may produce just the right antibody to destroy a pathogen that invades the body. To appreciate the capacity for antibody diversity, consider the

diverse combinations of things you create in your everyday life. A familiar example is making an ice-cream sundae. Imagine the varied combinations that are possible using 10 flavors of ice cream, 6 types of sauce, and 15 kinds of toppings.

Researchers have identified additional sources of antibody diversity. For example, the DNA of mature B cells that codes for the regions of immunoglobulins mutates very readily. These somatic mutations produce genes that code for slightly different antibodies.

We have used antibody diversity here as an example, but similar genetic mechanisms account for the diversity of T-cell receptors. Although we may actually use only a relatively few types of antibodies or T cells in a lifetime, the remarkable diversity of the immune system prepares it to attack most potentially harmful antigens that may invade the body.

Monoclonal antibodies are highly specific

Monoclonal antibodies are identical antibodies produced by cells cloned from a single cell. Each antibody reacts only with the same antigenic determinant (epitope) of the same antigen. Monoclonal antibodies are used in research and in medicine.

One way to produce monoclonal antibodies in the laboratory is to inject mice with the antigen of interest, such as an antigen

from a particular bacterium. After the mice have produced antibodies to the antigen, their plasma cells are collected. However, these normal plasma cells survive in culture for only a few generations, limiting the amount of antibody that can be produced. In contrast, cancer cells live and divide in tissue culture indefinitely.

B cells can be suspended in a culture medium together with lymphoma cells from other mice. (Lymphoma is a cancer of lymphocytes.) Then the B cells and lymphoma cells are induced to fuse. They form hybrid cells, known as **hybridomas**, which have properties of the two “parent” cells. Hybridomas can be cultured indefinitely (a cancer cell property) and continue to secrete antibodies (a B-cell property). Researchers select hybrid cells that are manufacturing the specific antibody needed and then clone them in a separate cell culture. Cells of this clone secrete large amounts of the particular antibody. Antibodies produced in this way are called *monoclonal antibodies*.

Immunologists also use recombinant DNA technology to produce monoclonal antibodies. Because of their purity and specificity, monoclonal antibodies have proved to be invaluable tools in modern biology. For example, a researcher may want to detect a specific molecule present in very small amounts in a mixture. The reaction of that molecule (the antigen) with a specific monoclonal antibody makes its presence

known. Monoclonal antibodies are used in similar ways in various diagnostic tests. Home pregnancy tests make use of a monoclonal antibody that is specific for human chorionic gonadotropin (hCG), a hormone produced by a developing human embryo (see Chapters 50 and 51). A dozen monoclonal antibodies are currently being used clinically to treat cancer. The drug Herceptin is a monoclonal antibody used in treating a type of breast cancer. Other monoclonal antibodies are used to treat autoimmune diseases, such as rheumatoid arthritis.

Immunological memory is responsible for long-term immunity

Immunological memory depends on memory B cells and memory T cells. Following an immune response, memory T cells group strategically in many nonlymphatic tissues, including the lung, liver, kidney, and intestine. Many infections occur at such sites, and T cells stationed in those locations can respond quickly. In response to antigen, memory T cells rapidly become T_C cells and produce substances that kill invading cells.

Memory B cells have a “survival gene” that prevents apoptosis, the programmed cell death that is the eventual fate of plasma cells. Memory B cells continue to live and produce small amounts of antibody long after the body has overcome an infection. This circulating antibody is part of the body’s arsenal of chemical weapons. If the same pathogen enters the body again, the antibody immediately targets it for destruction. At the same time, specific memory cells are stimulated to divide, producing new clones of plasma cells that produce the same antibody. The presence of circulating antibodies is used clinically to detect previous exposure to specific pathogens. For example, some HIV screening tests measure antibody to the virus that causes AIDS.

A secondary immune response is more effective than a primary response The first exposure to an antigen stimulates a **primary immune response**. An infection, or an antigen injected into an animal, causes specific antibodies to appear in the blood plasma in 3 to 14 days. After antigen injection, there is a brief *latent period* during which the antigen is recognized and appropriate lymphocytes begin to form clones. A *logarithmic phase* follows, during which the antibody concentration rises rapidly for several days until it reaches a peak (**FIG. 45-12**). IgM is the principal antibody synthesized during the primary immune response. Finally, there is a *decline phase*, during which the antibody concentration decreases to a very low level.

A second exposure to the same antigen, even years later, results in a **secondary immune response**. Because memory B cells bearing antibodies to that antigen (and also memory T cells with their specific T-cell receptors) persist for many years, the secondary immune response is much more rapid than the primary immune response and has a shorter latent period. Much less antigen is necessary to stimulate a secondary immune response than a primary response, and more antibodies are produced. In addition, the affinity of antibodies is generally much higher. The predominant antibody in a secondary immune response is IgG.

The body’s ability to launch a rapid, effective response during a second encounter with an antigen explains why we

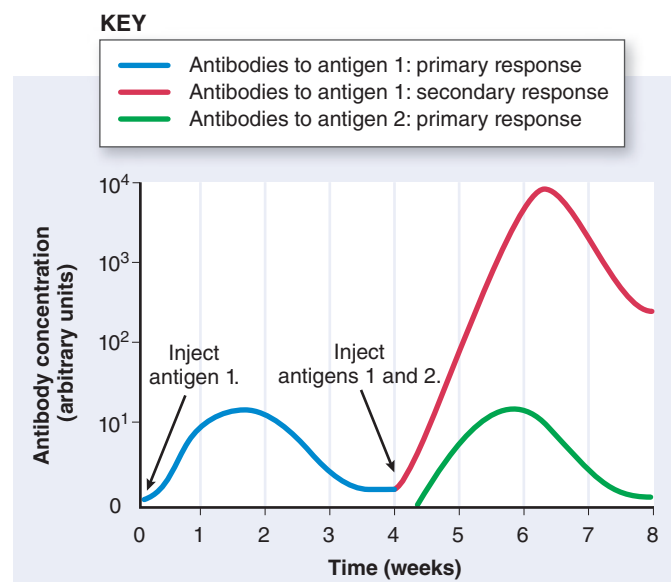

Figure 45-12 Immunological memory

Antigen 1 was injected at day 0, and the immune response was assessed by measuring levels of antibody specific for antigen 1. At week 4, the primary immune response had subsided. Antigen 1 was injected again, together with a new protein, antigen 2. The secondary immune response was greater and more rapid than the primary response. It was also specific to antigen 1. A primary immune response was made to the newly encountered antigen 2.

do not usually suffer from the same infectious disease several times. For example, a person who contracts measles or chickenpox is unlikely to become reinfected in the future. When someone is exposed a second time, the immune system responds quickly, destroying the pathogens before they have time to multiply and cause symptoms of the disease. Booster shots of vaccine are given to elicit a secondary immune response, thus reinforcing immunological memory.

You may wonder how a person can get influenza (the flu) or a cold more than once. The reason is that there are many varieties of these viral diseases, each caused by a virus with slightly different antigens. For example, more than 200 different viruses cause the common cold, and new varieties of cold and flu viruses evolve continuously by mutation (a survival mechanism for them). As viruses evolve, changes may occur in their surface antigens. Even a slight change may prevent recognition by memory cells. Because the immune system is so specific, each different antigen is treated by the body as a new immunological challenge.

Immunization induces active immunity We have been considering **active immunity**, which develops following exposure to antigens. Active immunity can be naturally or artificially induced (**TABLE 45-1**). If someone with influenza sneezes near you and you contract the disease, you develop active immunity naturally. Active immunity can also be artificially induced by *immunization*, that is, by exposure to antigens in a *vaccine*. When an effective vaccine is introduced into the body, the immune system actively develops clones of cells, produces antibodies, and develops memory cells.

Table 45-1 Active and Passive Immunity

Type of Immunity	When Developed	Development of Memory Cells	Duration of Immunity
ACTIVE			
Naturally induced	After pathogens enter the body through natural encounters (e.g., a person with influenza sneezes on you)	Yes	Many years
Artificially induced	After immunization with a vaccine	Yes	Many years
PASSIVE			
Naturally induced	After transfer of antibodies from mother to developing baby	No	Few months
Artificially induced	After injection with gamma globulin	No	Few months

The first vaccine was prepared in 1796 by British physician Edward Jenner against vaccinia, the cowpox virus. (The term *vaccination* was derived from the name of the cowpox virus.) Jenner's vaccine provided humans with immunity against the deadly disease smallpox, which closely resembles cowpox. Jenner had no knowledge of microorganisms or of immunology, and 100 years passed before French chemist Louis Pasteur began to develop scientific methods for preparing vaccines.
